

# Why Are Older Men Working More? The Role of Social Security

Zhixiu Yu\*  
University of Minnesota

July 17, 2021

## Abstract

The labor supply of older men increased from the 1930s to the 1950s cohort. This paper explores the role of three Social Security changes in determining these differences: increased normal retirement age, elimination of the earnings test, and increased delayed retirement credit, and evaluates the effects of several proposed reforms to the Social Security program on individuals' behaviors. I estimate a rich dynamic life-cycle model of labor supply, savings, and Social Security application for healthy and unhealthy people using the Method of Simulated Moments for the 1930s birth cohort. The model captures the key structure of the Social Security programs, pension systems, and time-varying income tax rates, while taking into account uncertainties in health status, survival rates, wages, and medical expenditures. My model matches well the observed life-cycle profiles of employment, hours worked by workers, and savings for healthy and unhealthy people from the Panel Study of Income Dynamics data. It shows that the joint effects of the three changed Social Security rules account for 73.4% and 88.7% of the observed rises in labor force participation and hours per worker by the 1950s cohort. Additional policy experiments suggest that postponing retirement age have little effect on older workers, while eliminating the earnings test and reducing retirement benefits would further increase older age participation by 3.37 and 5.10 percent, respectively.

Recent version of the paper can be obtained at <https://www.zhixiuyu.com>.

# 1. Introduction

Over the past several decades, the labor supply of older men in the United States has been rising dramatically, along both the intensive and extensive margins. For instance, data from the Current Population Survey (CPS) show that between 1995 and 2015, the labor force participation rates of men aged 65-69 increased by 10 percentage points: from 27% in 1995 to 37% in 2015.<sup>1</sup> Furthermore, annual hours worked by older workers increased by 15%, from 1,635 hours in 1995 to 1,878 hours in 2015.

The trend in older men's labor is particularly remarkable given that other age groups, such as younger men aged 21-55, exhibited a significant decline in work hours during the same period (Aguiar et al. (2018)).<sup>2</sup> During this time, Social Security rules in the United States have undergone some significant changes. For example, the normal retirement age (NRA) gradually increased from 65 to 67 for recent birth cohorts, the retirement earnings test (RET) was removed beyond the NRA for those 65 and older beginning in 2000, and the delayed retirement credits (DRC) rose from 3% to 8% for new cohorts.<sup>3</sup>

Why are Americans continuing to work into their late 60s? To what extent do the changes in the Social Security program rules account for the rise of the labor supply of older workers? Social Security is one of the most important social insurance programs for the elderly population in the United States. It provides benefits to retired workers, which constitute the majority of retirement income for persons aged 65 or older (Dushi et al. (2017)).<sup>4</sup> In 2019, the federal government spent \$1 trillion – about one-quarter of the annual federal budget – on providing insurance benefits to the 64 million Social Security beneficiaries, which accounted for 4.8% of the nation's gross domestic product (GDP).<sup>5</sup> As the U.S. population is aging rapidly, the fiscal solvency of public pension systems and social insurance programs provided by the government is under threat. The Old-Age and Survivors Insurance Trust Fund is projected to be depleted around 2034 under currently scheduled benefits and financing.<sup>6</sup> Therefore, understanding the role of Social Security on the recent increase

---

<sup>1</sup> Author's calculations from the CPS. See Figure D.1 in Appendix D for more details. These rises in the employment of older men are also documented in, e.g., Blau and Goodstein (2010) and Rogerson and Wallenius (2021).

<sup>2</sup> Using data from the CPS, Aguiar et al. (2018) show that, from 2000 to 2015, the annual hours worked by men aged 21-30 decreased by 203 hours, about 11.8%, and those by men aged 31-55 decreased by 168 hours, about 8.2%.

<sup>3</sup>NRA: The age at which beneficiaries are entitled to full benefits without a reduction based on age. RET: The provision requiring the withholding of retirement benefits if beneficiaries under NRA have earnings above certain exempt amounts. It applied to beneficiaries below age 70 before 2000. DRC: Retirement benefits are increased by a certain percentage (DRC) for each year if a worker delays the application beyond the NRA. See Section 3 for more information on Social Security rules.

<sup>4</sup>About 50% of Americans aged 65 or older live in households receiving over 50% of their family income from Social Security retirement benefits, and about 25% of them live in households receiving over 90% of their family income from retirement benefits. See more on Dushi et al. (2017).

<sup>5</sup>Source:<https://www.cbpp.org/research/federal-budget/where-do-our-federal-tax-dollars-go>.

<sup>6</sup>See Social Security Administration (2019) for more information on the projected financial status of Social Security programs.

in the labor supply of older workers and evaluating how further reforms to Social Security policies impact individual behaviors are essential for both older people's well-being and policy makers' decisions.

This research develops and estimates a structural model of labor supply and retirement that incorporates social insurance programs to: 1) examine the extent to which three changes in Social Security rules account for the rise in the labor supply of older men over time: increased NRA, elimination of the RET beyond the NRA, and increased DRC; and 2) evaluate the effects of several counterfactual Social Security policy reforms, such as postponing retirement ages, removing the earnings test, increasing payroll taxes, and reducing retirement benefits, on individual behaviors and well-being over the life cycle, such as savings, consumption, labor supply, and Social Security application. To do so, I focus on two cohorts of American men: those born in the 1930s and 1950s, which correspond to men aged 60-69 in the mid-1990s and mid-2010s, respectively.<sup>7</sup>

There are facts about these two cohorts that are important for analysis. Data from the Panel Study of Income Dynamics (PSID) show that the 1950s cohort, relative to the 1930s cohort, supplied more labor from age 60 to age 69, in terms of both labor participation rates and hours worked by workers. For instance, on average, participation rates at ages 60-69 for the 1950s cohort are 9.6 percentage points higher than those for the 1930s cohort, and hours worked by workers increased by 11.5% for the same age group between two cohorts. Moreover, comparing labor supply behaviors by health status over the life cycle between the 1930s and 1950s cohorts, I find that these increases in participation rates and hours worked across cohorts mainly result from people who were in good health.<sup>8</sup> In addition, compared to the older cohort, the younger cohort faced different Social Security rules: the NRA was postponed from age 65 to age 66, the RET was eliminated for individuals at the NRA or older, and the DRC was raised from around 4.5% to 8%.

To examine the role of changes in the Social Security rules on the increase in the labor supply of older men across cohorts, I first develop a dynamic life-cycle model for men who were born in the 1930s, which incorporates numerous details about the Social Security's Old-Age Insurance (retirement benefits) and Disability Insurance programs. Individuals choose how much to work (including participation) and consume, and whether and when to apply for Social Security benefits after they reach the early retirement age (ERA).<sup>9</sup> Individuals can receive benefits at a greater level if they delay the application. They also can work after receiving retirement benefits, but they will be subject to the earnings test.

---

<sup>7</sup>The 1930s cohort refers to individuals born in the period 1920-1935 whereas the 1950s cohort refers to those born in the period 1945-1960.

<sup>8</sup>Health status is measured using the self-reported work limitation conditions from the PSID. Respondents reported having no limitations or having limitations. I define those who are healthy or in good health as anyone who reports no limitations and those who are unhealthy as anyone who reports limitations. Details are in Section 5.1.2.

<sup>9</sup>ERA: the earliest age at which an individual can claim Social Security retirement benefits.

My model framework builds on French (2005), which accounts for Social Security, pensions, and uncertainty regarding health status, survival probabilities, and wages. I further develop French's model by adding heterogeneity in health and incorporating key features of Social Security disability benefits, health- and age-dependent medical expenditures, and a time-varying sequence of income taxes faced by a specific cohort.

More specifically, my model incorporates the following main innovations. First, I introduce a disabled state and assume that only individuals in that state are able to receive Social Security disability benefits. This assumption serves two purposes: 1) it distinguishes between unhealthy individuals as either temporarily sick or disabled; and 2) it accounts for the fact that disabled and non-disabled people face different economic environments over their lifetime. For instance, the U.S. government provides disability benefits to people who are unable to work due to a severe disability. By including the disability program, my model closely matches the observed profile of labor force participation of unhealthy people (including both temporarily sick and disabled people) over the life cycle much more closely than a model that fails to account for disability and disability benefits.<sup>10</sup> Second, I add out-of-pocket medical expenditures, which are uncertain and depend on age and health status, to capture the fact that unhealthy individuals need to spend much more on medical services over their lifespan (e.g., De Nardi et al. (2018)). Due to the uncertainty in medical expenditures, my model is able to match the observed differences in the savings profiles between healthy and unhealthy people over the life cycle.<sup>11</sup> Moreover, instead of using tax structures in one particular year to calibrate the tax parameters of the structural model, e.g., French (2005), I adapt a time-varying sequence of income tax rates faced by a specific cohort at each age during their lifetime, which is a function of annual earnings. It is intended to capture the progressive income taxes that change every year for a specific cohort (e.g., Borella et al. (2019a)). Hence, not only is my model richer, but it can also match more important life-cycle outcomes.

Next, I estimate my dynamic structural model for the 1930s cohort using the Method of Simulated Moments (MSM) and data from the Panel Study of Income Dynamics (PSID) and the Medical Expenditure Panel Survey (MEPS).

My estimated model matches the observed life-cycle profiles of labor force participation, hours worked by workers, and assets for healthy and unhealthy individuals for the 1930s cohort very well. I use it to examine the role of Social Security policy changes on the increase in the labor supply of older men between the 1930s and 1950s cohorts. Taking the estimated preference

---

<sup>10</sup>To simplify, individuals in my model do not make decisions on Social Security disability benefits application. I assume that disabled individuals receive disability benefits if their labor income is below a certain threshold and before age 65. For literature that explicitly models the Disability Insurance claiming, see, e.g., Low and Pistaferri (2015), Li (2018), and Michaud and Wiczer (2019).

<sup>11</sup>Instead of matching average savings profiles by health status, French (2005) estimates his model to match the mean and median savings profiles over the life cycle for all individuals.

parameters from the 1930s cohort as given, I apply the changed Social Security rules – normal retirement age, the earnings test, and delayed retirement credit – faced by the 1950s cohort to the estimated model of the 1930s cohort. My model shows that the joint effects of three changed rules explain 73.4% and 88.7% of the observed rises in the labor force participation and annual hours worked at ages 60-69, respectively, across cohorts. Of the three changed rules, eliminating the RET beyond the NRA contributes the most to these increases – it accounts for 71.1% of the rise in participation and 86.8% of the rise in the working hours at older ages. Shifting NRA from 65 to 66 only increases workers’ working hours before 66, and increasing the DRC by 3.5 percentage points has negligible effects on the labor behaviors at older ages.

Given the success of my estimated model in explaining labor supply behavior across cohorts, I then use my model to evaluate the impacts of several counterfactual policy reforms to the Social Security program. As reported by Social Security Administration (2019), due to rapid population aging caused by the large baby-boom generation entering retirement and lower-birthrate generations entering employment, Social Security benefits are expected to be payable in full on a timely basis until the mid-2030s. Thus, changes to the scheduled benefits and retirement policy for the Social Security program are needed.

I use my model to conduct three sets of counterfactual experiments. The first set of experiments delays the ERA by two years, from age 62 to 64, or postpones the NRA by two years, from age 66 to 68. The second set of experiments is to eliminate the RET for all beneficiaries under the NRA. In the third set of experiments, I raise the payroll tax rates by 1.57 percentage points or cut retirement benefits by 23%, as proposed by the Social Security Administration (2020).<sup>12</sup>

More specifically, I use my estimated model to evaluate these policy reforms’ effects on the labor supply, savings, consumption, and Social Security retirement benefits application behaviors for individuals. Also, to isolate the impact of these alternative reforms, I keep other Social Security rules and model parameters unchanged when I conduct each policy experiment.

My model’s predictions suggest that shifting the ERA has almost no effect on individual behaviors. Postponing the NRA to 68 will increase the reduction factor of retirement benefits in the early 60s and cause individuals to delay retirement. It will increase the average assets when individuals reach the ERA by 2.2% and annual hours worked at 60-69 by 0.72%, but its impact on the older age participation is small – only increase by 0.91 percentage points. In the second experiment, eliminating the RET will induce a 28-percentage-point increase in the fraction of benefits application at 62. In addition, consumption and older age participation will increase by 0.66% and 3.37%, respectively, especially for unhealthy people, whose participation at 60-69 will increase by 8.19%. In the third set of experiments, reducing benefits and raising the payroll taxes

---

<sup>12</sup>For more proposals and options to address the solvency problem of Social Security programs, see <https://www.ssa.gov/oact/solvency/index.html>.

both cause an increase in the hours worked at younger ages, 30-59, and a sizable decline in the fraction of early benefits applicants. However, raising the payroll tax will discourage the labor force participation over the life cycle and decrease both consumption and savings, whereas cutting benefits will increase the savings and the labor supply in both extensive and intensive margins over the life cycle. For instance, the participation at older ages will increase by 5.10% and the average assets at the ERA increase by 3.17%. Further, cutting benefits will cause a more significant decline in the fractions of early benefits applicants, which declined by 15 percentage points. Many will wait to apply for the benefits until the NRA to avoid further reduction due to early application.

This paper contributes to the literature on trends in older male workers' labor supply and retirement in three major ways: 1) it explores the increase in the labor supply of older workers, 2) it uses a structural model to explain those changes, and 3) it complements broader research on Social Security in the United States and globally.

More specifically, first, it contributes to the literature in documenting and explaining the increase in the labor supply of older men in the United States over the past few decades, including Schirle (2008) and Maestas and Zissimopoulos (2010). The former documents that the rise in the employment of older men has primarily been driven by an increase in that of older married men and examines the shared leisure effects of the increased wives' participation, whereas the latter paper studies the effects of shifts in the workforce skill composition on the rise of older men's participation. More recently, Rogerson and Wallenius (2021) present narratives stressing older female employment and institutional changes as the driving forces behind the rise of the employment of older males. I contribute to this literature by 1) documenting that the increases in the labor supply of older workers mainly result from people who were in good health, in terms of both participation and working hours, and 2) estimating the contribution of Social Security policy changes using a structural model. Compared to the reduced-form approach, a structural framework allows individuals to optimally choose and adjust their decisions when facing uncertainties, such as shocks to health status and medical expenditure, and different financial incentives for retirement, such as public pension and health insurance programs, over their life cycle (e.g., Rust and Phelan (1997), Casanova (2010) and Braun et al. (2017)). Further, it allows us to investigate individuals' behavioral responses to policy changes using estimated parameters (e.g., Imrohoroglu and Kitao (2012) and Haan and Prowse (2014)).

Second, this research is among the first to explain the observed changes in the labor supply and retirement behavior across different cohorts using structural models. Most existing studies examine a specific or representative cohort for the entire population to study labor supply and retirement behavior as a response to changes in the economic environment, e.g., Groneck and Wallenius (2017) and Fan et al. (2019). Using a structural model, Groneck and Wallenius (2017) find that Social Security auxiliary benefits have a sizable depressing effect on married women's

employment, whereas Fan et al. (2019) show that life-cycle human capital investment is critical for understanding life-cycle labor supply. My research contributes to the literature by filling this gap. Even though labor supply across cohorts has been studied in, e.g., Attanasio et al. (2008) and Park (2018), the population of interest is different. They investigate the between-cohort changes of women's behaviors; my paper focuses on the rise in older men's labor supply across cohorts, which few scholars have explored. Specifically, Bairoliya (2019) evaluates the impact of pension composition changes on the rise in labor supply of the elderly using a structural model over older ages. In contrast, I evaluate the labor supply effects of Social Security rules between cohorts using a whole life-cycle model that incorporates both the Old-Age and Disability Insurance programs of Social Security. Further, instead of explaining between-cohort labor behavior, Borella et al. (2019b) document the between-cohort changes in life expectancies, medical expenses, and wages per unit of human capital and uncover their effects on the labor market outcomes over the life cycle. My approach, by contrast, documents changes in the labor supply across cohorts and explain these changes using the changing economic environment.

Finally, my paper complements the extensive literature on analyzing the effects of Social Security or public pension reforms. French and Jones (2011) use their structural model to predict the impact of increasing the eligibility age for Social Security and Medicare on older male workers' retirement and show that the retirement effects of Social Security are more significant than those of Medicare. French (2005) highlights the significant work disincentives of the Social Security earnings test. My work complements these previous work by comparing two cohorts over time and with a richer model that includes heterogeneity in health and disability, which help to explain individual behaviors over the life cycle.<sup>13</sup>

The rest of the paper is organized as follows. Section 2 documents empirical facts about the recent trends in the labor supply for the 1930s and 1950s cohorts. Section 3 describes the changed Social Security rules faced by the 1950s cohort, relative to the 1930s one. Section 4 describes my structural model. Section 5 discusses the estimation procedure. Section 6 presents the estimation results of my model. Section 7 investigates how those changes in Social Security rules explain between-cohort changes in the labor supply using the estimated model. Section 8 evaluates the effects of several reforms to the Social Security rules on individual behaviors. Section 9 concludes.

---

<sup>13</sup>Instead of focusing on the U.S. social insurance programs, Erosa et al. (2012) and Laun and Wallenius (2016) document cross-country differences in the labor supply of the elderly and study the role of social insurance programs in these cross-country differences. In addition, there exists a large reduced-form literature exploiting the labor supply effects of Social Security rules, e.g., Friedberg (2000), Engelhardt and Kumar (2014), and Gelber et al. (2018).

## 2. Labor Market Outcomes Across Cohorts

In this section, I document the changes that occurred between the 1930s and 1950s cohorts in American men's labor supply over the life cycle.

### 2.1. Data

I use the 1968-2015 waves of the PSID and pick the cohort born in the 1930s (comprised of the 1920-1935 birth cohorts) and the 1950s one (comprised of the 1945-1960 birth cohorts). I use the labor supply, income, and health variables for the male household head from the PSID to construct the profiles of labor force participation and hours worked by workers over the life cycle. Appendix A reports more information about the data.

I start with 76,880 individuals and 3,075,200 observations. Following French (2005) and Borella et al. (2019b), I drop the Survey of Economic Opportunity (SEO)<sup>14</sup> sample to make the data more representative of the U.S. population, keep male household heads and their spouses, if present, and restrict the sample to ages 20-90. My resulting sample comprises 984 individuals and 20,091 observations for the 1930s cohort, and 2,844 individuals and 45,945 observations for the 1950s cohort. Table A.1 in Appendix A displays sample sizes before and after applying my selection criteria.

### 2.2. Life-Cycle Patterns

Figure 1 displays the resulting profiles of labor force participation and hours worked by workers (left and right panels, respectively) for ages 30-70 for both cohorts.<sup>15</sup> It shows that the participation and hours worked by workers decline steeply after age 60 for both cohorts, but that the 1950s cohort has higher participation rates and hours worked at older ages. For instance, on average, participation rates at ages 60-69 for the 1950s cohort are 9.6 percentage points higher than those for the 1930s cohort, and 15 percentage points higher for the age group 65-69. Moreover, between the 1930s and 1950s cohorts, hours worked by workers increased by 10.2% and 25.7% for age groups 60-69 and 65-69, respectively.

---

<sup>14</sup>The structure of the PSID started with two distinct samples. A nationally representative sample designed by the Survey Research Center became known as the SRC sample. A second sample of individuals was drawn from lower income levels, and this became known as the Survey of Economic Opportunity (SEO) sample.

<sup>15</sup>Labor force participation is defined as the fraction of individuals whose annual hours worked were more than 300. Hours worked is measured as of the survey. The profiles of participation and hours worked by workers are estimated by running a fixed-effect regression for each variable on a set of variables. I control for the birth-year effect, family effect, year effect, and individual effect to obtain the average profile in levels. Details are in Section 5.2.

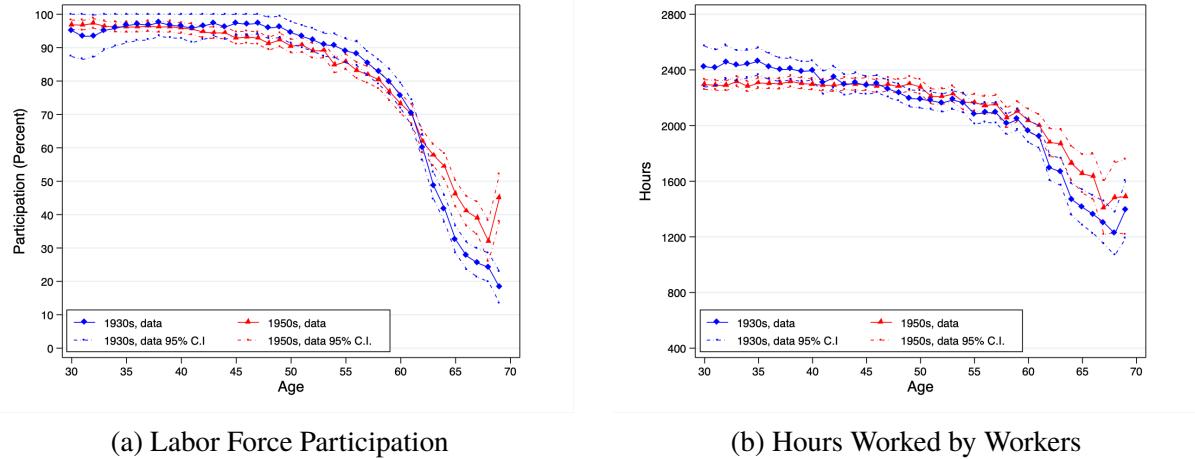

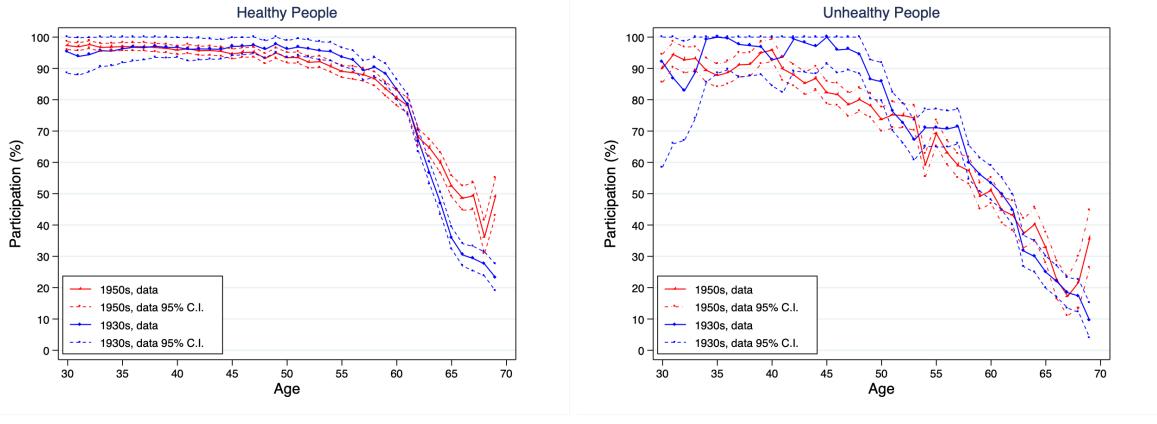

Fig. 1. Labor Supply Across Cohorts

Notes: Data profiles of life-cycle labor participation (panel a) and hours worked by workers (panel b), comparing the 1930s (blue) and the 1950s (red) cohorts for American men. The 95% confidence intervals are represented by dotted lines.

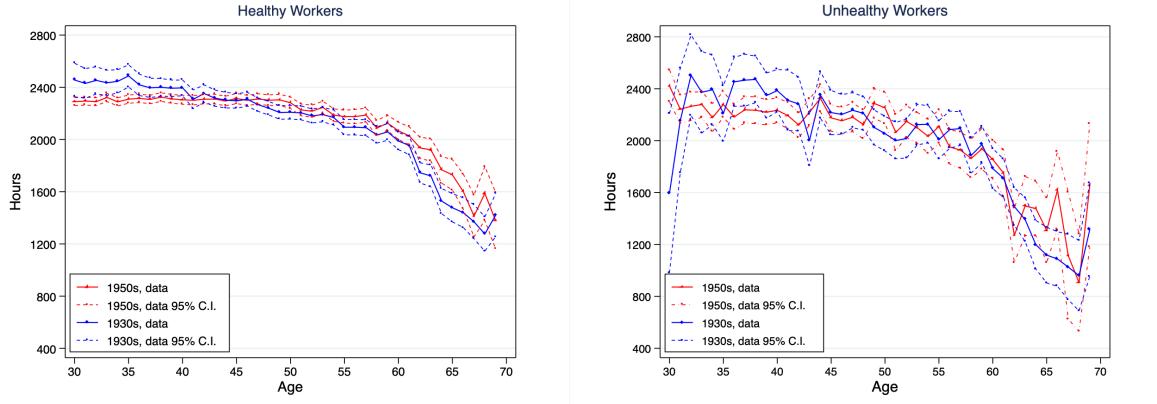

Data Source: Panel Study of Income Dynamics, author's calculations.

Figure 2 shows the life-cycle profiles of labor force participation and hours worked conditional on participation by health status (left panels: healthy; right panels: unhealthy). There are several patterns worth noticing. First, the effects of health status on labor supply are sizable over the life cycle. Participation rates of healthy people begin to decline around age 60 and decline sharply in the 60s. In contrast, the participation rates of unhealthy people start declining from age 40 and do so more slowly. At age 55, for example, the participation rate of unhealthy people is 23 percentage points lower than that of healthy people of the 1930s cohort. Second, the increases in participation rates and hours worked by older workers that occurred between the 1930s and 1950s cohorts mainly come from people in good health. The behavior of unhealthy people did not significantly change across cohorts.

These observed changes in labor force participation and hours worked profiles both motivate my research and are the target moments for my structural estimation. In the next section, I will discuss the changes in the Social Security rules faced by these two cohorts that are likely to be important determinants of labor supply and retirement choices.

Data Source: Panel Study of Income Dynamics, author's calculations.

### 3. Background: Changes in Social Security Rules

Social Security is the largest income-maintenance program in the United States. The Social Security trust funds are financed by payroll taxes on workers and provide insurance benefits to eligible workers and their families to replace, in part, the loss of income due to retirement, disability, or death. The trust funds consist of two parts. Retired workers, their families, and survivors of deceased workers receive retirement benefits under the Old-Age and Survivors Insurance (OASI) program. Disabled workers and their families receive disability benefits under the Disability Insurance (DI) program. As of 2020, about 180 million people worked and paid taxes and about 65 million people received Social Security benefits. Most of the beneficiaries are retirees and their families — about 49 million people.<sup>16</sup>

For American men aged 65 or older, Social Security is an essential source of retirement income. As reported in Social Security Administration (2021), retirement benefits replace about 78%, 42%, and 28% of pre-retirement income for very low earners, medium earners, and high earners, respectively, if they claim benefits at their NRA.

Workers are eligible to receive Social Security retirement benefits by paying payroll taxes on their wages during their working years. The amount of retirement benefits that a worker can receive depends on his Average Indexed Monthly Earnings (AIME), which is roughly a worker's average income based on his highest 35 years of earnings.<sup>17</sup> A formula is then applied to the AIME to calculate a worker's basic benefit, or Primary Insurance Amount (PIA), which is the amount to be received at the NRA. Workers can begin receiving retirement benefits after reaching the ERA of 62, but these benefits will be lower if workers claim them before the NRA. In contrast, benefits will be higher (by a certain percentage – DRC) if workers delay the application beyond the NRA and up until age 70. Both NRA and DRC vary by year of birth, whereas the ERA is the same for everyone. In addition, workers are allowed to work for pay while receiving retirement benefits, but they are subject to an earnings test, which causes a reduction of the benefits level in that period. Thus, the NRA, DRC, and the age at which the earnings test applies are essential factors affecting workers' labor supply and retirement decisions at older ages. In what follows, I describe the observed changes in the Social Security rules faced by American men born in the 1950s compared with those born in the 1930s.

Using data from the Social Security Administration (SSA), I summarize NRA and DRC for people born between 1920 and 1960 in columns (1) and (2) of Table 1. Compared to the

---

<sup>17</sup>An individual's earnings up to two years before eligibility (currently age 60) are indexed to average wage growth to ensure that a worker's future benefits reflect the general rise in the standard of living that occurred during his working lifetime. Years with no earnings are entered into the average as 0s. After age 60, nominal earnings are used in the benefit formula without any indexation. See Social Security Advisory Board, December 2010 for more information.

Table 1: Social Security Rules for People Born in 1920-1960

Year of Birth	NRA (1)	DRC (%) (2)	RET (3)
1920 - 1924	65	3	70
1925 - 1926	65	3.5	70
1927 - 1928	65	4	70
1929 - 1930	65	4.5	70
1931 - 1932	65	5	70
1933 - 1934	65	5.5	70
1935 - 1936	65	6	NRA
1937	65	6.5	NRA
1938	65 and 2 months	6.5	NRA
1939	65 and 4 months	7	NRA
1940	65 and 6 months	7	NRA
1941	65 and 8 months	7.5	NRA
1942	65 and 10 months	7.5	NRA
1943 - 1954	66	8	NRA
1955	66 and 2 months	8	NRA
1956	66 and 4 months	8	NRA
1957	66 and 6 months	8	NRA
1958	66 and 8 months	8	NRA
1959	66 and 10 months	8	NRA
1960 or Later	67	8	NRA

<sup>1</sup> Notes: Columns 1 and 2 report the normal retirement age and delayed retirement credit faced by individuals in each birth cohort. Column 3 reports the age that the retirement earnings test is removed.

Table 2: Effects of Early or Delayed Social Security Claiming

Cohort	NRA	DRC(%)	Benefit, as a percentage of PIA, payable at age								
			62	63	64	65	66	67	68	69	70
1930s	65	4.5	80	86.67	93.33	100	104.5	109	113.5	118	122.5
1950s	66	8	75	80	86.67	93.33	100	108	116	124	132

<sup>1</sup> Notes: Table shows the Social Security retirement benefits, expressed as the percentage of Primary Insurance Amount, that an individual can receive if he claims at ages 62-70.

<sup>2</sup> Source: Social Security Administration, author's calculations.

1930s cohort with NRA of 65 and DRC of 4.5% on average, the younger cohort has NRA at age 66 and DRC of 8% on average. For instance, if a person in the younger cohort retires one year after the NRA, his retirement benefits will increase by 8% permanently. In contrast, if a person in the older cohort retires one year after the NRA, his retirement benefits only increase by 4.5%, on average. Table 2 summarizes the effects of applying for retirement benefits at ages 62-70, which

are expressed as the percentage of unreduced benefits at the NRA, under different rules of NRA and DRC faced by the two cohorts.

Workers from the 1930s cohort can get 80% of their full retirement benefits at 62 and 122.5% of benefits at 70, whereas workers from the 1950s cohort can only receive 75% of their full retirement benefits at 62, which is 5 percentage points lower than the older cohort, but 132% of benefits at 70, which is 9.5 percentage points higher than 1930s cohort. Therefore, both changes in the NRA and DRC encourage the younger cohort to work more at older ages and delay retirement.

Moreover, from the year 2000, there has been a change in the retirement earnings test, which prevented workers from collecting their retirement benefits while simultaneously earning money from working. Before 2000, workers who had reached age 62 but had not yet reached 70 were subject to the RET. More specifically, retired workers from the 1930s cohort who already collected their retirement benefits faced a 50% tax rate on their labor income between age 62 and the NRA and a 33% tax rate between the NRA and age 70, until all their retirement benefits were taxed out. Although the benefits lost due to the earnings test could be recouped in the future, these high income rates discouraged workers' labor supply.<sup>18</sup> After 2000, however, this earnings test was removed for individuals beyond the NRA. Only workers under the NRA are subject to the earnings test at a 50% tax rate. The ages at which the RET is removed for people born between 1920 and 1960 are summarized in column (3) of Table 1. Hence, workers in the younger cohort who reached the NRA can keep both their retirement benefits and labor income without reduction, as long as their income is below a certain threshold. Therefore, eliminating the RET beyond the NRA encourages workers to work more at older ages.

## 4. The Model

This section describes a dynamic life-cycle model of consumption, labor supply, and Social Security claiming which incorporates the key aspects of the Social Security's Old-Age Insurance and Disability Insurance programs.

Time is discrete and indexed by  $t$ . A model period is one year long. Consider a male household head seeking to maximize his expected lifetime utility at age  $t$ ,  $t = t_0, t_1, t_2, \dots, T$ . People enter the model at age 25 and they live up to a maximum age of 95. In each time period (or age)  $t$ , a male household head faces uncertainty in health and disability status, mortality risk, wages, and medical expenditure. Individuals make decisions on how much to consume, how much to work

---

<sup>18</sup>Beneficiaries can recoup the benefits lost due to the earnings test in the future. For example, benefits are recalculated at the NRA to account for periods in which earnings tests were applied. This benefit re-computation adjusts the actuarial reduction for early application and results in a permanently higher benefit for retired workers.

(including both labor force participation and hours worked decisions), and whether to apply for Social Security retirement benefits (if eligible).<sup>19</sup>

#### 4.1. Preferences

Each individual in period  $t$  derives utility from consumption,  $c_t$  and leisure,  $l_t$ . The within-period utility function from consumption and leisure is given by:

$$u(c_t, l_t) = \frac{1}{1-\nu} (c_t^\gamma l_t^{1-\gamma})^{1-\nu} \quad (1)$$

where  $\gamma$  is between 0 and 1 and  $\nu$  is positive. The parameter  $\gamma$  is the weight on consumption. Individuals with a higher value of  $\gamma$  have stronger preferences for work. The parameter  $\nu$  is the coefficient of relative risk aversion (CRRA) and controls the intertemporal substitutability of consumption and leisure. Individuals with a higher value of  $\nu$  become less willing to intertemporally substitute. The parameter  $\nu$  also measures the non-separability between consumption and leisure. Under perfect foresight and positive consumption and working hours,  $\nu > 1$  implies that consumption and leisure are Frisch substitutes (see Low (2005) and French and Jones (2011)).

Leisure in period  $t$  is given by:

$$l_t = L_t - n_t - \theta_p^{h_t} p_t - \phi \mathbb{1}_{\{h_t \neq 0\}} \quad (2)$$

where  $L_t$  is an individual's total annual time endowment;  $n_t$  is hours worked;  $p_t$  is a 0-1 indicator of participation in the labor market that is equal to 1 when  $n_t$  is positive and zero otherwise;  $\theta_p$  is the fixed cost of working (measured in hours per year). It includes time spent getting ready for work, including commuting time.<sup>20</sup> I allow the fixed cost to depend on health and disability status,  $h_t \in \{0, 1, 2\}$ , which takes three values and can be good health (healthy) ( $h_t = 0$ ), bad health (unhealthy) ( $h_t = 1$ ), or disability (unhealthy) ( $h_t = 2$ ). In this model, retirement arises endogenously as part of the labor participation decision, and individuals can reenter the labor market. Moreover, there will be an amount of leisure loss due to unhealthy status,  $\phi$ , which is measured in hours per year. It captures the time spent in physical therapy, doctor visiting, etc. Therefore, compared to healthy individuals, people who are unhealthy face different fixed costs of working and have lower available time even if they do not work.<sup>21</sup>

---

<sup>19</sup>The model framework follows French (2005) and French and Jones (2011).

<sup>20</sup>Fixed costs help us capture that very few people work a very small number of hours.

<sup>21</sup>I assume that unhealthy individuals ( $h_t = 1, 2$ ) share the same fixed cost of working  $\theta_p^{h_t}$  and leisure loss  $\phi$ .

## 4.2. Health, Disability, Mortality, and Medical Spending

In each time period, individuals face uncertainty in health,  $h_t \in \{0, 1, 2\}$ , with 0 being in good health, 1 being in bad health, and 2 being in a disabled state. Health in the next period,  $h_{t+1} \in \{0, 1, 2\}$ , depends on the individual's current health and age, and evolves according to the Markov chain between three states, with an age-dependent Markov transition matrix. A typical element of the health transition matrix at age  $t$  is given by:

$$\pi_{j,i,t+1} = Pr(h_{t+1} = j | h_t = i, t + 1), \quad i, j \in \{0, 1, 2\} \quad (3)$$

The lifespan is uncertain. Let  $s_{t+1}$  denote the probability that an individual is alive at age  $t + 1$  conditional on being alive at age  $t$ . The survival probability depends on age and previous health status, as:  $s_{t+1} = S(h_t, t + 1)$ . Because individuals live up to a maximum age  $T$ ,  $s_{T+1} = 0$  for any  $h$ .

Let  $m_t$  denote the out-of-pocket medical expenditure at age  $t$ , which depends on age and health status, i.e.,  $m_t = M(h_t, t)$ . The  $m_t$  is defined as the individual's total medical expenditure net of medical coverage provided by insurance, such as Medicaid, Medicare, etc.<sup>22</sup> Age- and health-dependent medical expenditure are intended to capture the fact that people spend more on out-of-pocket medical services as they age or health status gets worse (e.g., De Nardi et al. (2018)).

## 4.3. Wages and Spousal Earnings

The logarithm of hourly wages at age  $t$ ,  $\ln w_t$ , is a function of health status and age,  $W(h_t, t)$ , and an autoregressive component of wages,  $\omega_t$ , as follows:

$$\ln w_t = W(h_t, t) + \omega_t \quad (4)$$

$$\omega_t = \rho \omega_{t-1} + \eta_t, \quad \eta_t \sim N(0, \sigma_\rho^2) \quad (5)$$

The autoregressive component  $\omega_t$  has the correlation coefficient,  $\rho$ , and a normally distributed innovation,  $\eta$ . For more details about the function  $W(h_t, t)$  and stochastic components  $(\rho, \sigma_\rho^2)$ , see Section 5.1.5.

Spousal earnings are modeled as a function of a male household head's wages, age, and health status:

$$ys_t = ys(w_t, h_t, t) \quad (6)$$

---

<sup>22</sup>Health insurance status and types are explicitly modeled in, e.g., Imrohoroglu and Kitao (2012) and Blau and Gilleskie (2008).

which can serve as insurance against uncertainties over the life cycle. The details of the function  $ys(\cdot)$  are in Section 5.1.6.

#### 4.4. Social Security and Pension Benefits

Social Security benefits are modeled in great detail to match the current U.S. system. Once an individual reaches the ERA, he becomes eligible to claim Social Security retirement benefits. Social Security application decision is a one-time decision and irreversible. Individuals receive no retirement benefits before claiming. Upon applying, individuals collect the benefits (subject to the earnings test),  $ss_t$ , until their death. As discussed earlier in Section 3, the lifetime career earnings ( $AIME_t$ ), claiming age, and labor income after collecting benefits (through the earnings test) are the three main factors affecting an individual's retirement benefits.

First, the level of retirement benefits depends on an individual's  $AIME$ , which are calculated using the average of his highest 35 years of earnings. This causes work incentives to drop after 35 years in the labor market, since for the workers who have been working more than 35 years, working an additional year will increase their  $AIME$  only if their labor income exceeds the lowest earnings in some previous years. Let  $aime_t$  denote the annualized measure of  $AIME$ . Since individuals are assumed to enter the model at age 25,  $aime_t$  evolves according to

$$aime_{t+1} = \begin{cases} \max\{aime_t + \frac{w_{tn_t}}{35}, aime_{max}\} & \text{if age} < 60 \\ \max\{aime_t + \max\{0, \frac{w_{tn_t} - aime_t}{35}\}, aime_{max}\} & \text{if age} \geq 60 \end{cases} \quad (7)$$

where  $aime_{max}$  denotes the threshold in which  $aime_t$  is capped. Then  $PIA_t$  is computed using a piecewise linear function of  $aime_t$  given as follows.

$$\begin{aligned} PIA_t = & 0.9 * \min\{aime_t, aime_0\} \\ & + 0.32 * \min\{\max\{aime_t - aime_0, 0\}, aime_1 - aime_0\} \\ & + 0.15 * \max\{aime_t - aime_1, 0\} \end{aligned} \quad (8)$$

where  $aime_0$  and  $aime_1$  denote the bend points in the PIA formula, following rules from the Social Security Administration. This formula replaces a higher percentage of the pre-retirement earnings for workers with low average career earnings than for workers with high average career earnings.

Second, the age at which individuals apply for Social Security retirement benefits also affects the level of benefits. These effects are summarized in Table 2 in Section 3.

Third, beneficiaries under age 70 are subject to the earnings test. That is, if they receive labor income that exceeds the earnings threshold  $y_{ret}$  while collecting retirement benefits, each dollar of labor income above  $y_{ret}$  leads to a  $\tau_{ret}$  dollar decrease in retirement benefits until all the benefits have been taxed away. Thus, the final amount of benefits,  $ss_t$ , that an individual receives

at age  $t$  is

$$ss_t = \max\{0, ssb_t - \tau_{ret} * \max\{0, (w_t n_t - y_{ret})\}\} \quad \text{if age} < 70 \quad (9)$$

where  $ssb_t$  is the amount of  $PIA_t$  adjusted by early/delayed application for retirement benefits. Note that those benefits lost due to the RET are credited to future benefits.<sup>23</sup>

Individuals who are disabled,  $h_t = 2$ , receive Social Security disability benefits before NRA if their labor income is below a certain value  $y_{db}$ . Disability benefits  $db_t$  are calculated in the same way as retirement benefits, i.e.,  $db_t = PIA_t$ , but there is no early penalty rate. Upon reaching the NRA, disability benefits automatically convert to retirement benefits.

In this study, pension benefits,  $pb_t$ , are modeled in the same way as in French (2005),

$$pb_t = pb(PIA_t) \quad (10)$$

where  $pb_t$  is imputed as a function Social Security benefits. Similar to Social Security benefits,  $pb_t$  depends on the individual's lifetime career earnings and is illiquid until age 62. Unlike Social Security benefits,  $pb_t$  is not affected by early/delayed Social Security application and earnings test, and pension accrual rates are higher in the 50s and lower at other ages for individuals. These are all captured and adjusted in modeling pension benefits. See French (2005) for more details.

#### 4.5. Budget Constraint

In each time period, an individual receives income through interest on assets,  $ra_t$ ; labor income,  $w_t n_t$ ; spousal earnings,  $ys_t$ ; pension benefits,  $pb_t$ ; Social Security retirement benefits net of the earnings test (if applicable),  $ss_t$ ; Social Security disability benefits (if applicable),  $db_t$ , and government transfers (if applicable),  $tr_t$ . The budget constraint faced by a household head is given by:

$$\begin{aligned} a_{t+1} = & a_t + \underbrace{y_t(r a_t + w_t n_t + y_s t + p b_t) - T_t(y_t, \tau_t) - T_t^{ss}(w_t n_t, \tau_t^{ss})}_{Y_t(y_t, \tau_t, \tau_t^{ss})} \\ & + (b_t * ss_t) + db_t \mathbb{1}_{\{h_t=2\}} + tr_t - m_t - c_t \end{aligned} \quad (11)$$

where  $b_t \in \{0, 1\}$  is an indicator variable that takes a value one if the individual has claimed the retirement benefits and zero otherwise. The term  $y_t(r a_t + w_t n_t + y_s t + p b_t)$  is the annual taxable income in period  $t$ , where  $r$  is the pre-tax risk-free interest rate;  $T_t(\cdot)$  presents taxes paid on income in period  $t$ , which is a function of taxable income  $y_t$  and tax rate  $\tau_t$ ; and  $T_t^{ss}$  denotes the payroll tax paid on labor income, which depends on labor income  $w_t n_t$  and tax rate  $\tau_t^{ss}$ . Let  $Y_t(\cdot)$  denote the

---

<sup>23</sup>Following French and Jones (2011), if a year's worth of benefits are withheld due to the RET between the ERA and (NRA-1), benefits in the future are increased by 6.67%, the actuarial reduction factor for early application. If a year's worth of benefits withheld due to the RET between the NRA to 70, benefits in the future are increased by DRC.

after-tax income. Details of taxes are in Section 4.6.

Individuals also face the borrowing constraint,

$$a_{t+1} \geq 0. \quad (12)$$

It is illegal to borrow against Social Security benefits and difficult to borrow against most forms of pension wealth.

Government transfers,  $tr_t$ , provide a consumption floor  $\underline{c}$ , as in Hubbard et al. (1995) and De Nardi et al. (2010), such that

$$tr_t = \min\{0, \underline{c} + m_t - (a_t + Y_t + ss_t + db_t)\}. \quad (13)$$

They imply that individuals can consume at least at a minimum level,  $\underline{c}$ , which captures the federal safety net programs in the United States, such as Food Stamp, Supplemental Security Income, etc.<sup>24</sup>

#### 4.6. Taxes

Individuals in a cohort face the effective time-varying income tax rate over their life cycle.<sup>25</sup> As in Bénabou (2002) and Borella et al. (2019a), effective tax rates depend on age (time) and taxes paid on annual income  $y_t$  are given by:

$$T_t(y_t, \tau_t) = (1 - \lambda_t y_t^{-\tau_t}) * y_t \quad (14)$$

where  $y_t(ra_t + w_t n_t + ys_t + pb_t)$  from Equation (11);  $\tau_t$  denotes the degree of progressivity; and  $\lambda_t$  denotes the average level of taxation. For tractability, I assume that individuals anticipate changes in the effective tax rates on total income.

Moreover, workers pay the payroll taxes on labor income to help finance Social Security and Medicare, hence, there is a payroll tax rate  $\tau_t^{ss}$  on the worker's labor income  $w_t n_t$ , up to a threshold  $\bar{y}_t^{ss}$  in each period. Then the amount paid for the payroll tax at age  $t$  are given by:

$$T_t^{ss}(w_t n_t, \tau_t^{ss}) = \tau_t^{ss} * \min[w_t n_t, \bar{y}_t^{ss}] \quad (15)$$

---

<sup>24</sup>Braun et al. (2017) and Kopecky and Koreshkova (2014) explicitly model the means-tested social insurance programmes that provide agents with a guaranteed minimum level of consumption, such as Supplemental Security Income and Food Stamp programs.

<sup>25</sup>I do not model the budget for the government because I consider only one cohort, and it is unclear that whether the budget constraint is balanced at the cohort level.

## 4.7. Recursive Formulation

The life cycle can be divided into three stages for each individual. The first stage is between ages 25 and 61: individuals are not eligible for pension and Social Security retirement benefits and only decide on consumption and hours worked (including participation). Let  $X_t = (a_t, w_t, h_t, aime_t)$  denotes the vector of state variables at age  $t$ , it includes: asset,  $a_t$ ; wage,  $w_t$ ; health and disability status,  $h_t$ ; and Social Security wealth,  $aime_t$ . Since spousal earnings, out-of-pocket medical expenditure, and pension benefits depend on other state variables, they are not included in  $X_t$  explicitly. In recursive form, the individual's problem in state ( $X$ ) and age  $t$  can be written as:

$$\begin{aligned} V_t(X_t) &= \max_{c_t, n_t} \{u(c_t, l_t) + \beta s_{t+1} E_t[V_{t+1}(X_{t+1})] + \beta(1 - s_{t+1})B(a_t)\} \\ &= \max_{c_t, n_t} \left\{ \frac{1}{1-\nu} \left( c_t^\gamma [L_t - n_t - \theta_p^{h_t} p_t - \phi \mathbb{1}_{\{h_t \neq 0\}}]_t^{1-\gamma} \right)^{1-\nu} \right. \\ &\quad \left. + \beta s_{t+1} \int V_{t+1}(X_{t+1}) dF(X_{t+1}|X_t, t, c_t, n_t) + \beta(1 - s_{t+1})B(a_{t+1}) \right\} \end{aligned} \quad (16)$$

subject to Equations (3)-(15). The parameter  $\beta$  is the discount factor. Individuals with higher values of  $\beta$  are more patient and more willing to defer their consumption and leisure. The function  $F(\cdot|\cdot)$  determines the conditional distribution of state variables, given (3)-(15).

When an individual dies, any remaining assets,  $a_t$ , are left to his heirs. Following De Nardi (2004), an individual who dies values bequest of the leftover assets,  $a_t$ , according to a bequest function  $B(a_t)$ , which takes the form:

$$B(a_t) = \theta_b \frac{(a_t + \kappa)^{(1-\nu)\gamma}}{1 - \nu} \quad (17)$$

The parameter  $\theta_b$  is the bequest weight and determines the strength of the bequest motive. It determines the marginal propensity to consume out of wealth in the final period of life. The term  $\kappa$  is the bequest shifter and measures the curvature of the bequest function. Individuals with a higher value of  $\kappa$  treat the bequest more like of a luxury good. There is infinite disutility of leaving non-positive bequests if  $\kappa = 0$ , while the utility of a zero bequest is finite if  $\kappa > 0$ .<sup>26</sup>

The second stage is between ages 62-69, a transition period where individuals choose consumption, labor supply, and whether to apply for Social Security retirement benefits. The value

---

<sup>26</sup>French and Jones (2011) show that the bequest parameters  $\theta_b$  and  $\kappa$  are identified largely from the top asset quantile. When  $\kappa$  is large, the marginal utility of bequests will be lower than of consumption, unless the individual is rich.

function of the individual in state ( $X_t$ ) is described as:

$$\begin{aligned} V_t(X_t) = \max_{c_t, n_t, b_t} & \left\{ \frac{1}{1-\nu} (c_t^\gamma [L_t - n_t - \theta_p^{h_t} p_t - \phi \mathbb{1}_{\{h_t \neq 0\}}]_t^{1-\gamma})^{1-\nu} \right. \\ & + \beta s_{t+1} \int V_{t+1}(X_{t+1}) dF(X_{t+1}|X_t, t, c_t, n_t, b_t) \\ & \left. + \beta(1 - s_{t+1}) B(a_{t+1}) \right\} \end{aligned} \quad (18)$$

subject to Equations (3)-(15). The state vector  $X_t = (a_t, w_t, h_t, b_{t-1}, aime_t)$  and the indicator  $b_{t-1}$  denotes Social Security benefits claim status.

The third stage is between ages 70-95, an entire retirement period where individuals only decide on consumption. Since Social Security rules provide no incentive to delay retirement benefit application after reach age 70, I assume that all workers retire and apply for Social Security benefits by age 70, i.e., for  $t \geq 70$ ,  $b_t = 1$ ,  $n_t = p_t = 0$ . Then the individual's value function during the entire retirement period is given as follows:

$$\begin{aligned} V_t(X_t) = \max_{c_t} & \left\{ \frac{1}{1-\nu} (c_t^\gamma [L_t - \phi \mathbb{1}_{\{h_t=1\}}]_t^{1-\gamma})^{1-\nu} \right. \\ & \left. + \beta s_{t+1} \int V_{t+1}(X_{t+1}) dF(X_{t+1}|X_t, t, c_t) + \beta(1 - s_{t+1}) B(a_{t+1}) \right\} \end{aligned} \quad (19)$$

subject to Equations (3), (6)-(14). The vector of state variables  $X_t = (a_t, h_t, aime_t)$ .

The model is solved backwards using value function iteration. An individual's decisions in period  $t$  depend on his state variables  $X_t$ , preferences  $\Theta = (\gamma, \nu, \theta_p^{h=0}, \theta_p^{h \neq 0}, \phi, L, \beta, \theta_b, \kappa)$ , and parameters that determine the data generating process for the state variables  $\chi = (r, \sigma_\eta^2, \rho, W(h_t, t+1), \{\pi_{h_{t+1}, h_t, t}\}_{t=1}^T, \{s_t\}_{t=1}^T, \{y_{s_t}\}_{t=1}^T, \{m_t\}_{t=1}^T, \{pb_t\}_{t=1}^T, \{ss_t\}_{t=1}^T, \{db_t\}_{t=1}^T, Y_t(\cdot))$ .

The solution to a male household head's problem consists of sequences of consumption rules  $\{c_t(X_t, \Theta, \chi)\}_{1 \leq t \leq T}$ , hours worked rules  $\{n_t(X_t, \Theta, \chi)\}_{1 \leq t \leq T}$ , and Social Security benefit application rules  $\{b_t(X_t, \Theta, \chi)\}_{1 \leq t \leq T}$  that solve problems (16)-(19). The labor force participation rules at  $t$ ,  $p_t(X_t, \Theta, \chi)$ , is equal to zero when  $n_t(X_t, \Theta, \chi) = 0$  and equal to one otherwise. Assets in the next period,  $a_{t+1}(X_t, \Theta, \chi)$ , can be obtained by inserting these decision rules into the asset accumulation equation (11). See Appendix B for more details on my computations.

## 5. Estimation

I estimate my model using a two-step Method of Simulated Moments (MSM) estimation strategy, as used by French (2005), French and Jones (2011), and Gourinchas and Parker (2002). In

the first step, I estimate or calibrate the parameters that can be cleanly identified without explicitly using my model,  $\chi$ .

In the second step, I use the Generalized Method of Moments (GMM) techniques to estimate the remaining preference parameters,  $\Theta = (\gamma, \nu, \theta_p^{h=0}, \theta_p^{h \neq 0}, \phi, L, \beta, \theta_b, \kappa)$ , taking  $\chi$  as given. The objective of the MSM is to find a vector of parameters  $\Theta$  that generates simulated decision profiles that *best match* (measured by a GMM criterion function) the corresponding profiles from the data. In this paper, I require my model to match the life-cycle profiles of participation, hours worked conditional on participation, and savings by health from the PSID for the 1930s cohort. The following sections describe these two steps in more detail.

## 5.1. *First-Step*

The parameters estimated in the first step include health transitions, survival probabilities, out-of-pocket medical spending, spousal earnings, wage profiles, wage process, the interest rate, and consumption floor, and initial distributions of state variables, such as savings, AIME, and health status. I estimate or calibrate using data and existing literature evidence. Table 3 provides a summary of the first-step inputs. I set the consumption floor  $c$  to \$3,500 (in 1987 dollars), and the pre-tax interest rate  $r$  is set to 4%, as in French (2005).<sup>27</sup>

### 5.1.1. *Data*

I primarily use two data sets for my model estimation: the Panel Study of Income Dynamics (PSID) and the Medical Expenditure Panel Survey (MEPS).

The PSID is a longitudinal study of a representative sample of the U.S. population. The study began in 1968 with a nationally representative sample of 18,000 individuals belonging to 5,000 families. Researchers interviewed these individuals and their descendants on an annual basis (biennial since 1997), collecting information on, among other things, labor market behaviors, income, health status, and wealth. I use the 1968-2015 waves of PSID to construct my sample of American men. The resulting sample comprises 984 individuals and 20,091 observations.

The MEPS is a nationally representative survey of families, individuals, their medical providers and employers across the United States. It provides very detailed data on medical expenditures, sources of payment, health insurance coverage, health status, and demographic and

---

<sup>27</sup>I tried computing time-varying interest rates faced by the 1930s cohort using the procedure adopted in De Nardi et al. (2010). I computed the real return over the years 1976-2016 using returns from stock (adjusted using S&P 500 indexes), CD, bond, and housing (adjusted using FHFA). The computed time-varying interest parameters did not change the estimation results.

Table 3: First-Step Parameters Summary

Parameter	Description	Value	Source
<b>Budget Constraints</b>			
$r$	Real interest rate	4%	French (2005)
$ys(\cdot)$	Spousal earnings	text	PSID
$\underline{c}$	Consumption floor	\$3,500	French and Jones (2011)
$aime_t$	Social Security wealth	text	SSA

$aime_{max}$	Maximum Social Security wealth	\$43,800	SSA
$ERA$	Early retirement age	62	SSA
$NRA$	Normal retirement age	65	SSA
$DRC$	Delayed retirement credit	4.5%	SSA
	Retirement Earnings Test	Under NRA	NRA-69
$\tau_{ret}$	Tax rate	50%	33%
$y_{ret}$	Threshold	\$6,000	\$8,186
			SSA

<sup>1</sup> Notes: Monetary values are expressed in 1987 dollars.

<sup>2</sup> Data Source: Medical Expenditure Panel Survey, Social Security Administration, and Panel Study of Income Dynamics, author's calculations.

socio-economic characteristics. I use data from the 1999–2012 waves of MEPS to estimate the profiles of medical expenditure. I drop the observations with missing values of relevant variables, e.g., age, medical spending, or health insurance. The resulting sample comprises 120,731 persons and 211,709 person-year observations. See Appendix A for more information on data and my sample selection.

### 5.1.2. Health Transitions

Health and disability status is measured based on the following set of self-reported questions from the PSID. Respondents in year  $t$  report (1) *Do you have any physical or nervous condition that limits the type of work or the amount of work that you can do?* (2) *Does this condition keep you from doing some types of work?* (3) *For work you can do, how much does it limit the amount of work you can do – a lot, somewhat, or just a little?*<sup>28</sup>

Following Low and Pistaferri (2015), I define those who are in good health ( $h_t = 0$ ) as anyone who reports “No” to the first question or “Not at all” to the third question; those who are in bad health ( $h_t = 1$ ) as anyone who reports “Yes” to the first question and “Somewhat” or “Just a little” to the third question; and those who are in a disabled state ( $h_t = 2$ ) as anyone who reports “Yes” to the first question, “Can do nothing” to the second questions, and “A lot” to the third question, which intends to meet the SSA criterion on disability insurance qualification.<sup>29</sup>

Since there are three health states,  $h_t = \{0, 1, 2\}$ , we have nine transition patterns,  $Pr(h_t = j|h_{t-1} = i)$ ,  $i, j \in \{0, 1, 2\}$ . I estimate the evolution of health for individuals in the 1930s cohort by running a probit regression for an indicator ( $h_t = j|h_{t-1} = i$ ) on age dummies using the sample with ( $h_{t-1} = i$ ). The predicted values of these probit regressions are the estimates of  $Pr(h_t = j|h_{t-1} = i)$ ,  $i, j \in \{0, 1, 2\}$ . I linearly interpolate the probabilities of transitioning in three states across ages so that the transition matrices changes smoothly over the life cycle. Figure 3 displays the age-specific health transition out of good health status  $Pr(h_t|h_{t-1} = 0)$ , and the remaining transitions are reported in Figure D.2 in Appendix D.

The probabilities of staying healthy decline over the life cycle, and the drop is more rapid at older ages. For instance, the probability of staying in good health decreases from 99% at age 30 to 90% around age 65 and 80% around age 80. The decline is mostly absorbed by increasing probabilities of transitioning into bad health, which increase with age, and the increase is faster at older ages.

---

<sup>28</sup>The possible answers to the first question are “Yes” or “No”; to the second question are “Yes”, “No”, or “Can do nothing”; to the third question are “Not at all”, “Somewhat”, “Just a little”, or “A lot” after 1976, and “I can’t work”, “It limits me a lot”, “Some, not much”, or “Limitation, but not on work” before 1976.

<sup>29</sup>Since the second question became available from 1986, I define the health status based on the first and third questions before 1986.

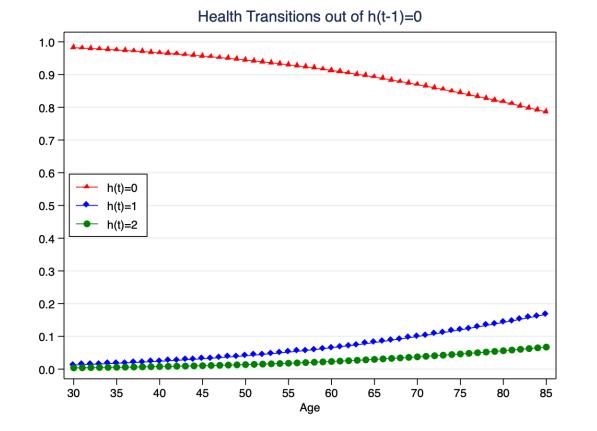

Fig. 3. Health Transitions - The probabilities of transitioning out of good health

Notes: The red line shows the transition probabilities from good health to good health. The blue line shows the transition probabilities from good health to bad health. The green line shows the transition probabilities from good health to disability status.

Source: Panel Study of Income Dynamics, author's calculations.

### 5.1.3. Survival Probabilities

Age- and health-dependent survival probabilities are estimated by running a logistic regression for the indicator of survival on age polynomial, previous health status, and interaction between cohort dummies and these variables whenever they are statistically significant, using data from the PSID. The estimated coefficients are reported in Table C.1 in Appendix C.<sup>30</sup>

Figure 3 displays the estimated mortality rates by age and health status.<sup>31</sup> Mortality rates increase over the life cycle for both healthy and unhealthy types. The increase is extremely quick for the unhealthy type at older ages, even though healthy and unhealthy types start from very similar levels.

### 5.1.4. Out-of-Pocket Medical Expenses

The out-of-pocket medical expenses are computed as total medical expenditure net of the amount covered by health insurance programs, using data from the MEPS. Health status is measured

<sup>30</sup>Due to the small sample size of joint event ( $s_t = 0 | h_{t-1} = 2$ ), I assume that unhealthy individuals ( $h = 1, 2$ ) face the same survival/mortality rates at each age.

<sup>31</sup>As French (2005) discussed, the PSID underestimates mortality rates by 25%. I adjusted my estimated mortality rates by multiplying 1.25 for my model estimation.

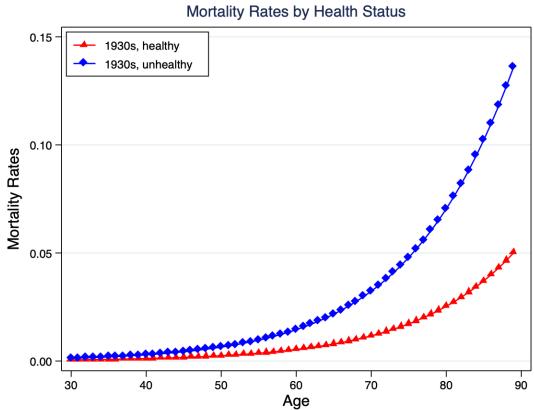

Fig. 4. Mortality Rates by Health Status

Notes: The blue line shows the probability of dying next period when unhealthy. The red line shows the probability of dying next period when healthy.

Source: Panel Study of Income Dynamics, author's calculations.

based on self-perceived health rank (e.g., Pashchenko and Porapakkarm (2019)), which ranges from 1 to 5.<sup>32</sup> I estimate the out-of-pocket expenditure in the following steps.

First, I estimate the profiles of total medical expenditure by running a weighted regression on age dummies and year dummies, separately for individuals in each health status.<sup>33</sup> Then I estimate the profiles of coverage rates (ratio of the amount covered by insurance programs and the total medical expenditure) by regressing them on age dummies and year dummies, separately by health status. For working-age individuals (age 25-64), the medical coverage is computed as the amount paid by private insurance programs or Medicaid. In contrast, for individuals who are 65 or older, the coverage is calculated as the expenses paid by Medicare. Next, I compute the out-of-pocket expenditure as the product of estimated un-coverage rates and total medical expenses at each age and health status.<sup>34</sup> Last, I smooth my estimated profiles by regressing them on a quadratic function of age.

Figure 5 displays the smoothed life-cycle profiles of the out-of-pocket medical expenses by

<sup>32</sup>The MEPS survey has three waves in each year  $t$ , and in each wave respondents rank their health as (1) *excellent*, (2) *very good*, (3) *good*, (4) *fair*, or (5) *poor*. Individuals whose health rank falls in the first three categories in all three waves are referred to people in good health ( $h_t = 0$ ); individuals with health rank falls in the last category in any wave are referred to as disabled people ( $h_t = 2$ ); and the rest are referred to as people in bad health ( $h_t = 1$ ).

<sup>33</sup>Following the procedure used by Pashchenko and Porapakkarm (2019), I use the cross-sectional weights and longitudinal weights provided by MEPS in the estimation.

<sup>34</sup>Following De Nardi et al. (2018), the estimated medical expenses are multiplied by 1.60 for people younger than 65 years old and by 1.90 for people who are 65 or older to make medical spending consistent with the aggregate medical expenditures from the National Health Expenditure Account (NHEA).

health status. The difference in medical cost by health is sizable. For example, at age 80, the average annual out-of-pocket medical expenses are about \$17,000 for disabled people, which are \$6,000 higher than those for people in bad health and \$9,000 higher than those for people in good health.

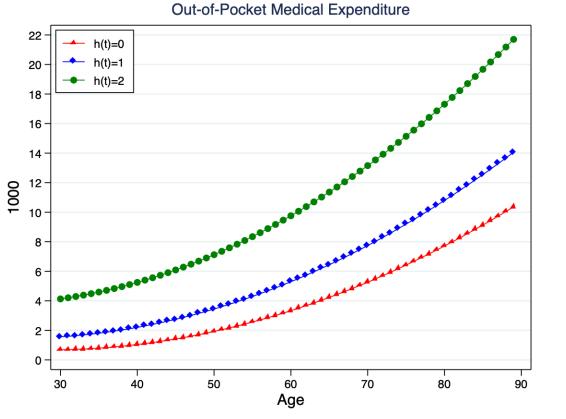

Fig. 5. Out-of-Pocket Medical Expenditure by Health Status

Notes: The red line shows the out-of-pocket expenditure for people in good health. The blue line shows that for people in bad health. The green line shows that for people in disabled state. Monetary values are expressed in 2016 dollars.  
Source: Panel Study of Income Dynamics, author's calculations.

### 5.1.5. Hourly Wages

Hourly wages are computed as annual earnings divided by annual hours worked, using data from the PSID. Respondents in year  $t$  report their annual earnings and hours worked in year  $t - 1$ .

As described in the model section, the deterministic wage profiles  $W(h_t, t)$  depend on the individual's age and health. Since wages are only observed for labor market participants in the data, to adjust selection bias in observed wages, I estimate hourly wage profiles using the two-stage Heckman selection model (Heckman (1976)), as used by Guner et al. (2012) and Bairoliya (2019). In the first step, I estimate the labor force participation (selection equation) by running a probit regression using all observations from the PSID, and an inverse Mill's ratio is generated. In the second step, I estimate hourly wage by running a regression on age polynomials, the intersection of health and age polynomials, and the inverse Mill's ratio obtained from the first step.<sup>35</sup> The estimated coefficients of the two-stage procedure are reported in Table C.2 in Appendix C.

<sup>35</sup>I drop the observations with hourly wages below \$6.50 or above \$250 (in 2016 dollars) when I estimate the wage profiles, to control the minimum wage and high wage outliers, similar to the selection used by French (2005) and Borella et al. (2019b).

Figure 6 displays smoothed wage profiles by health status. Several features are worth noticing. First, hourly wage rates peak for men around age 50. Second, the hourly wage rates of people in good health are higher than those of people in bad health, which are higher than those of disabled people, over the life cycle. For example, around age 50, a healthy individual's hourly wages are \$5 higher than those of people in bad health and \$9 higher than those of disabled people.

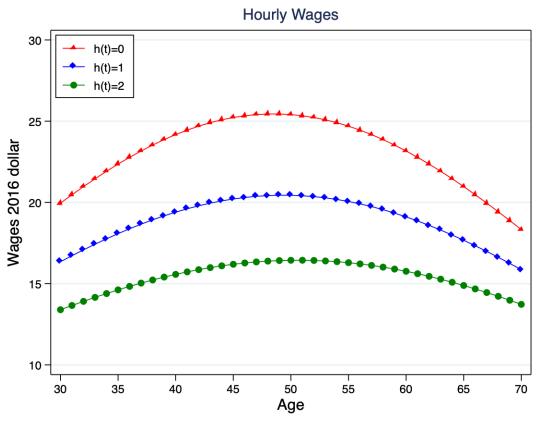

Fig. 6. Hourly Wages by Health and Disability Status

Notes: The red line shows the hourly wages for people in good health. The blue line shows those for people in bad health. The green line shows those for people in disabled state. Monetary values are expressed in 2016 dollars.

Source: Panel Study of Income Dynamics, author's calculations.

I estimate the stochastic components of hourly wages – the autoregressive coefficient and variance of wage shocks ( $\rho, \sigma_\rho^2$ ), using the wage residuals from the above steps. Following the procedure described in Borella et al. (2019b), I limit the age range between 30 and 75 and drop the highest 0.5% residuals to avoid large outliers that inflate the variance. The estimation process is performed by Maximum Likelihood and standard Kalman Filter recursions. The estimated results for  $(\rho, \sigma_\rho^2)$  in wages are  $(0.99, 0.0125)$ , which are consistent to the estimates of French (2005) and Borella et al. (2019b).

The estimated stochastic components of wages and deterministic age- and health-specific profiles are used in Equation (4) of the Model Section 4 to simulate wages and fed into the model estimation.

### 5.1.6. Spousal Earnings

Spousal earnings are defined as annual earnings from the PSID. Respondents in year  $t$  report their wife's total annual earnings in year  $t - 1$ . I estimate  $ys(\cdot)$  by running a fixed-effects regression on male household head's age polynomial, logarithm hourly wages, and health and disability status.<sup>36</sup> The estimated coefficients are reported in Table C.3 of Appendix C.

### 5.1.7. Social Security and Taxes

From the Social Security Administration, individuals in the the 1930s cohort face the ERA of 62, NRA of 65, DRC of 4.5% on average, bend points in the PIA formula \$3,720 and \$22,392 (in 1987 collars), and the maximum AIME of \$43,800 (in 1987 dollars).<sup>37</sup> The tax rate and exempt amount of earnings test are different for the following two age groups under age 70. 1). For Social Security beneficiaries under age 65, \$1 in retirement benefits will be withheld for each \$2 of labor income above the annual exempt amount, \$6,000 in 1987 dollars. 2). For beneficiaries aged 65 and over, \$1 in benefits will be withheld for each \$3 of labor income above the exempt amount, \$8,186 in 1987 dollars.

For Social Security disability benefits, I assume that disabled individuals can receive the disability benefits if they are over age 50 and their labor income is less than \$3,600 (in 1987 dollars).<sup>38</sup> This assumption captures the monthly substantial gainful activity amount of \$300, which the SSA sets for the non-blind disabled people to be eligible for the disability benefits.

Further, individuals have to pay federal tax and payroll tax on total income and labor income. The effective time-varying marginal tax rates on American men's total income are estimated using data from the PSID for the 1930s cohort, e.g., Borella et al. (2019a).<sup>39</sup> For the time-varying payroll tax rates and threshold values on labor income, I take the tax rates for Social Security's Old-Age, Survivors, and Disability Insurance (OASID) and for Medicare's Hospital Insurance (HI) using data from the SSA. From 1960 to now, the sum of OASID and HI tax rates for each employee and employer varies from 3% to 7.65%.

---

<sup>36</sup>To estimate the average profiles, I treat wife's earnings as zero for individuals who are single.

<sup>37</sup>The DRC faced by the 1930s cohort varies from 3% to 6%, depending on the year of birth. I take the average DRC, 4.5%, into my model estimation. The bend points in the PIA formula and the maximum AIME are taken from the rules of 1987.

<sup>38</sup>As Low and Pistaferri (2015) modeled, individuals apply for disability insurance with probabilities, which depend on age and health status. To capture the average disability benefits received by individuals, I assume that disabled people receive  $\pi^{db} \times db_t$  if they are eligible, where  $\pi^{db}$  is taken from Low and Pistaferri (2015) for old age groups with severe work limitation.

<sup>39</sup>I thank Nicolò Russo for help on the tax estimation.

### 5.1.8. Initial Distribution

To compute the initial distribution of the relevant state variables at age 30, I take random draws from the empirical joint distribution of wages, health, and household assets for male household heads aged 28-32 from the PSID data for the 1930s cohort. I adjust the mean of log wages for good health, bad health, and disabled state to match the estimated wage profiles for each health status. For initial Social Security wealth  $aime_{30}$ , I assume that all individuals enter the labor market at age 25 and work 2,000 hours per year at the hourly wage rate of age 30 to impute for initial values of AIME, following the procedure used by French (2005). Table C.4 in Appendix C summarizes the initial distribution of assets, wages, and health status. It shows that individuals in good health have higher wages and assets than those in bad health and disability status.

## 5.2. Target Profiles

The profiles of labor force participation, hours worked by workers, and savings by health status that my model is estimated to match are constructed using the data from the PSID.

Labor force participation is a dummy variable and counted as one if the individual's annual hours worked are more than 300 hours per year. Hours worked are measure with self-reported working hours from the survey. Respondents in survey year  $t$  report their total hours of work in year  $t - 1$ .<sup>40</sup> The measurement of assets includes real estate, the value of a farm or business, vehicles, stocks, mutual funds, IRAs, Keoghs, liquid assets, bonds, and investment trusts, net of mortgages and other debts. It does not include pension or Social Security wealth. I define assets as the sum of all above asset types, plus the value of home equity, and net of debts.<sup>41</sup>

I estimate the target profiles by running the following fixed-effects regression:

$$Z_{it} = f_i + \sum_{k=1}^T B_{gk} I\{age_{it} = k\} \times I\{h_{it} = 0\} + \sum_{k=1}^T B_{bk} I\{age_{it} = k\} \times I\{h_{it} \neq 0\} \\ + \sum_{f=1}^F B_f family size_{it} + B_u U_t + u_{it} \quad (20)$$

---

<sup>40</sup>Following French (2005), hours are counted as zero if the reported annual hours worked are below 300 hours.

<sup>41</sup>I exclude the extremely wealthy or poor observations in the top 5% and bottom 1% of the sample. Assets in the PSID have only been observed in 1984, 1989, 1994, 1999, 2001, 2003, 2005, 2007 PSID wealth surveys, and 2009, 2011, 2013, 2015 PSID family files. To impute the assets in the missing years, I run the fixed-effect regression for assets on a set of variables, including age polynomials, its interaction with health status, and with log wages, family size, education, unemployment rates, a dummy for health status, its interaction with unemployment rates, and with log wages (e.g., Borella et al. (2019b)). I then use the imputed and the actual observations to estimate the assets profiles by health status that are used as target moments and to compute the initial joint distribution.

where  $Z_{it}$  represents the data observation of either assets, hours worked, or participation for individual  $i$  at age  $t$ ;  $f_i$  is denotes an individual-specific effect;  $\text{familysize}_{it}$  is family size dummies;  $U_t$  is the unemployment rate; and  $\{\{B_{gk}\}_{k=1}^T, \{B_{bk}\}_{k=1}^T, \{B_f\}_{f=1}^F, B_u\}$  are parameters. Since the data observations with disability status are small, I combine observations in bad health with disabled states into *unhealthy* ( $h_t = 1, 2$ ). Thus, the target profiles are only estimated by healthy ( $h = 0$ ) and unhealthy ( $h \neq 0$ ) status.<sup>42</sup> Figure 7 displays the estimated target profiles by health status.

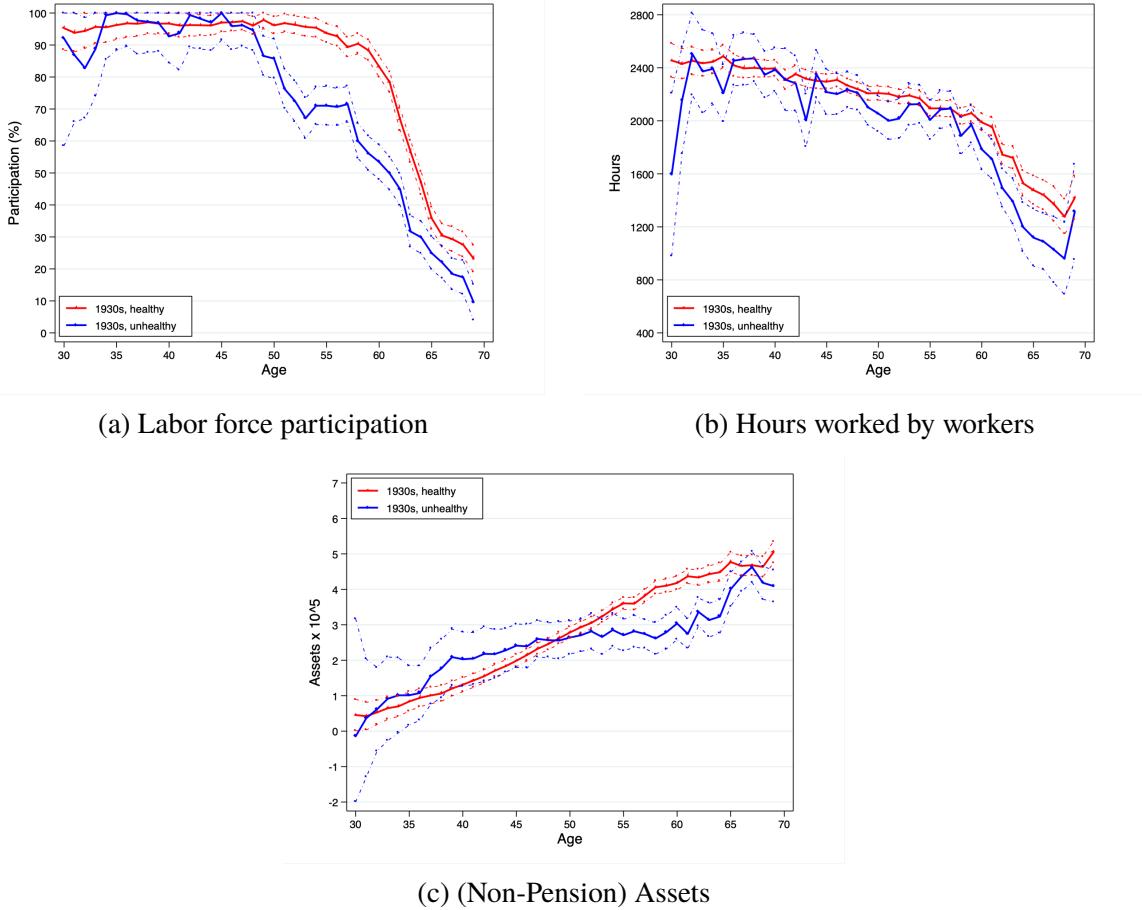

Fig. 7. Target Profiles

Notes: Panel a shows the profiles of labor force participation by health status. Panel b shows the profiles of hours worked by health status. Panel c shows the profiles of assets by health status. The red lines represent the profiles for healthy people ( $h = 0$ ). The blue lines represent the profiles for unhealthy people ( $h = 1, 2$ ). Monetary values are expressed in 2016 dollars.

Source: Panel Study of Income Dynamics, author's calculations.

<sup>42</sup>Following the procedure adopted in French (2005), to make the target profiles that my model is estimated to match are no contaminated by family, year, and individual-specific effects, I control for family size and year (business cycle) effects by setting the family size to 3 and the unemployment rate to 6.5%. Further, I use the mean individual-specific effect for individuals who are age 50, have the average level of health at age 50, and born in 1930, to control for birth-year (cohort) effect and correlation between person-specific effect and health status for the 1930s cohort. See French (2005) for a more detailed discussion on the estimation strategy.

As discussed in Section 2, health status has sizable effects on labor supply. For example, participation rates of healthy individuals start declining in their 60s, while those of unhealthy people begin in their late 40s (panel a). One potential explanation is that disability benefits provide unhealthy people incentives to drop out of the labor market because of the labor income limitation on receiving benefits.

In Figure 7 (panel b), health does not have a notable impact on annual working hours during the working period, 30-59, but it affects labor behaviors after age 60, at which workers begin working less. For example, at age 65, an average healthy worker works about 400 hours more than an average unhealthy worker.

Figure 7 (panel c) shows that health has large effects on savings behaviors for individuals after age 50. An average healthy person has about \$120,000 (in 2016 dollars) more than an average unhealthy person at age 60. Part of the difference can be explained in medical expenditure, which is more expensive for unhealthy people at older ages.

### 5.3. Second Step

In the second step, I use GMM techniques to estimate the remaining nine preference parameters  $\Theta = (\gamma, \nu, \theta_p^{h=0}, \theta_p^{h=1,2}, \phi, L, \beta, \theta_b, \kappa)$  and find a vector of preference parameters  $\hat{\Theta}$  that minimizes the weighted distance between the estimated target profiles from the PSID and the simulated profiles generated by the model. The moments that my model is estimated to match are shown as follows:

1. Labor force participation by health status (healthy and unhealthy) and ages (30-69), resulting in  $2\mathbb{T}$  moment conditions.
2. Hours worked conditional on participation by health status (healthy and unhealthy) and ages (30-69), resulting in  $2\mathbb{T}$  moment conditions.
3. Mean non-pension assets by health status (healthy and unhealthy) and ages (30-69), resulting in  $2\mathbb{T}$  moment conditions.<sup>43</sup>

This gives a total of  $6 \times \mathbb{T} = 240$  moment conditions. Then the MSM estimator  $\hat{\Theta}$  is given by the minimized GMM criterion function:

$$\hat{\Theta} = \arg \min_{\Theta} \frac{I}{1 + \tau} \hat{\varphi}(\Theta; \chi)' \hat{\mathbf{W}}_I \hat{\varphi}(\Theta; \chi) \quad (21)$$

where  $\tau$  is the ratio of the number of observations to the number of simulated observations and  $\hat{\varphi}(\Theta; \chi)$  is a  $6\mathbb{T}$ -element vector of moment conditions, such that

---

<sup>43</sup> As Borella et al. (2019b) discussed, individuals save against uncertainties and for retirement, thus, matching assets is essential to evaluate the effect of policy instruments and other forces.

$$\hat{\varphi}(\Theta; \chi) = \begin{bmatrix} E[p_{iht}|h, t] - \int p_t(X, \Theta, \chi) dF_{h,t}(X|h, t) \\ E[n_{iht}|h, t] - \int n_t(X, \Theta, \chi) dF_{h,t}(X|h, t) \\ E[a_{iht}|h, t] - \int a_t(X, \Theta, \chi) dF_{h,t-1}(X|h, t) \end{bmatrix}_{t \in \{30, \dots, 69\}, h \in \{\text{healthy, unhealthy}\}}$$

where  $E[p_{iht}|\cdot]$ ,  $E[n_{iht}|\cdot]$ , and  $E[a_{iht}|\cdot]$  are estimated from the PSID, whereas  $\int p_t(X, \Theta, \chi) dF(\cdot)$ ,  $\int n_t(X, \Theta, \chi) dF(\cdot)$  and  $\int a_t(X, \Theta, \chi) dF(\cdot)$  are generated by the model.  $F_{ht}(\cdot)$  indicates the CDF of the state variables at period  $t$  given health status  $h$ . Further, the estimated weighting matrix,  $\hat{\mathbf{W}}_I$ , is the inverse of a  $6\mathbb{T} \times 6\mathbb{T}$  diagonal matrix, which consists the elements of the variance-covariance matrix from the data along its main diagonal.

In summary, I proceed with the MSM as follows.

1. Estimate the life-cycle profiles for labor force participation, hours worked, and assets by health status from the data.
2. Estimate the initial distribution for relevant state variables and a set of parameters that determine the data generating process for the state variables,  $\chi$ , as in the first step. Then taking as given  $\chi$ , generate matrices of health and wage shocks.
3. Iterate on the following procedure for different values of  $\Theta$  until the minimum distance, as in Equation (21), has been found.
  - (a) Given  $\Theta$ , solve the model and generate the simulated life-cycle profiles for decision variables.
  - (b) Compute moment conditions and calculate the distance between the simulated profiles and data profiles described in Equation (21).
  - (c) Pick a new vector of preference parameters,  $\Theta_{new}$ , and repeat the above two steps.

## 6. Estimation Results

Table 4 presents the estimated preference parameters from the MSM. My estimation results suggest that the annual time endowments are 5,275 hours, and the hours of leisure loss due to unhealthy status are 102 hours. They imply that unhealthy status induces about 2% loss in total available time per year, and people in bad health and disability status spend, on average, 102 hours in activities such as visiting the doctor. These estimates are consistent with the estimation of previous life-cycle literature, e.g., De Nardi et al. (2010) and Bairoliya (2019).<sup>44</sup>

---

<sup>44</sup>See French (2005) and French and Jones (2011) for a detailed discussion on the identification of preference parameters.

Table 4: Preference Parameter Estimates

Parameter	Definition	Estimates	S.E.
$\gamma$	Consumption weight	0.52	0.0034
$\nu$	CRRA for flow utility	4.79	0.0509
$\beta$	Time discount factor	0.96	0.0030
$L$	Leisure endowment	5275	49.12
$\phi$	Hours of leisure lost, unhealthy	102	4.36
$\theta_p^{h=0}$	Fixed cost of work, healthy	924	13.87
$\theta_p^{h=1,2}$	Fixed cost of work, unhealthy	751	12.66
$\theta_B$	Bequest weight	0.039	0.0001
$\kappa$	Curvature of the bequest	51k	2k

The fixed cost of working is often assumed to be the same for workers regardless of health status (e.g., French (2005)). My estimates show that the fixed costs of working for healthy and unhealthy workers are 924 and 751 hours per year, respectively. This implies that the labor market costs about 17.5% of the time for healthy people and 14.5% of the time for unhealthy people. That is because workers in bad health and disability status prefer to work at a job with less commuting time or a part-time job with a flexible schedule. In the PSID, the annual hours traveling to work for unhealthy workers are about 80 hours less than those for healthy workers.<sup>45</sup> Thus, my estimation on fixed costs are consistent to those in the PSID.

## 6.1. Model Fit

Figure 8 displays both the life-cycle profiles of decision variables (including 95% confidence intervals) from the PSID and the model simulation for the 1930s cohort. The model fits those targeted data profiles very well and reproduces the key observed patterns of participation, hours worked, and savings for both healthy and unhealthy individuals over their life cycle.

Moreover, Figure 9 provides additional evidence on how well my model's simulated profiles fit into the untargeted profiles of individuals' behaviors – the average levels of labor force participation, workers' hours worked, and non-pension savings – over the life cycle.

---

<sup>45</sup>The question in the PSID is *Head's travel to work time in annual hours*.

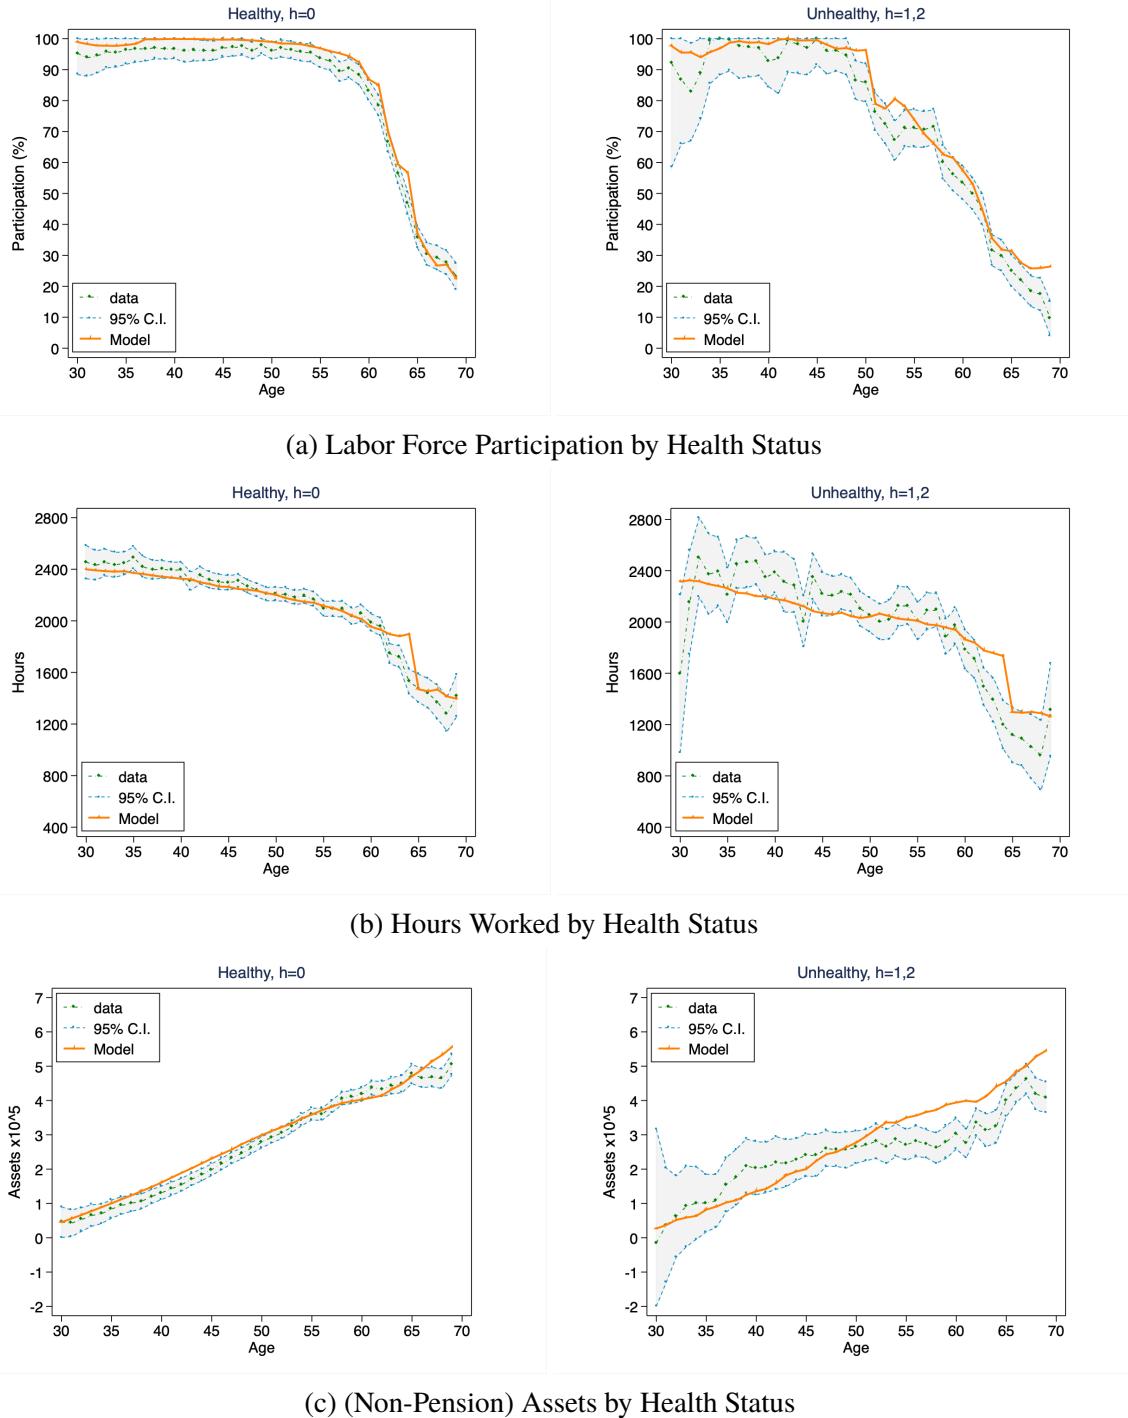

Fig. 8. Model v.s. Data Profiles: Targeted Moments

Notes: Panel a shows the model fit for labor force participation by health status. Panel b shows the model fit for hours worked conditional on participation by health status. Panel c shows the model fit for non-pension assets by health status. Profiles for healthy people ( $h = 0$ ) are on the left, whereas profiles for unhealthy people ( $h = 1, 2$ ) are on the right. Model profiles are represented by the orange lines. Data profiles with 95% confidence intervals are represented by the shaded area. Monetary values are expressed in 2016 dollars.

Data Source: Panel Study of Income Dynamics, author's calculations.

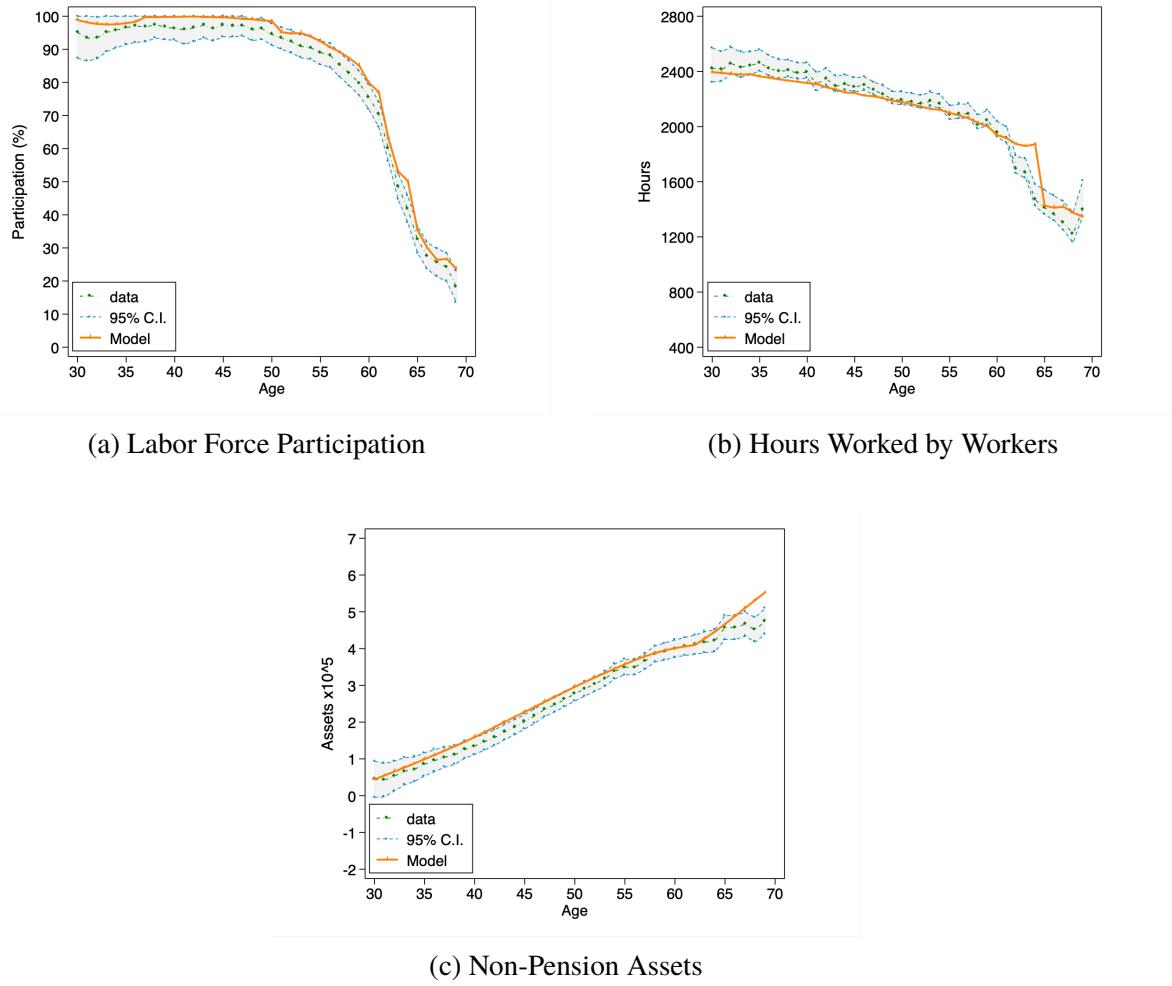

Fig. 9. Model v.s. Data Profiles: Overall Labor Supply and Savings

Notes: Panel a shows the model fit for the average profile of labor force participation. Panel b shows that for hours worked conditional on participation. Panel c shows that for non-pension assets. Model profiles are represented by the orange lines. Data profiles with 95% confidence intervals are represented by the shaded area. Monetary values are expressed in 2016 dollars.

Data Source: Panel Study of Income Dynamics, author's calculations.

## 7. Explaining Trends in Labor Supply of Older Men

In this section, I use my estimated model from Section 6 to evaluate the extent to which the changes in the Social Security rules account for the rise of older workers' labor supply between the 1930s and 1950s cohorts, described in Section 2.<sup>46</sup> Taking the estimated preference parameters from the 1930s model as given, I replace the Social Security rules with those faced by the 1950s cohort and simulate how the 1930s cohort would behave if they had the same values for those factors as the 1950s cohort. Table 5 reports their effects on participation and hours worked decisions at older ages. Figure 10 displays the effects of changing each Social Security rule on the labor market behaviors over the life cycle at the average level and compares the model-simulated changes with the data profiles across two cohorts (Figure 11 and Figure 12 display their effects by health status).

Increasing NRA from age 65 to age 66 has a small impact on labor supply behaviors, which increases the participation and hours worked at 60-69 by 4.16% and 2.31%, respectively. As Figure 10 (panel a) displays, it only makes people stay in the labor market for one more year to get full retirement benefits. It does not provide additional incentives for individuals to work more after reaching the new NRA. In addition, the impact on the hours worked decision is similar for both healthy and unhealthy workers (see Figure 11 (panel a)), but the effect on the participation decision is much smaller for unhealthy people. As shown in Table 5, increasing the NRA to 66 causes the participation rates at 65-69 to increase by 10.43% and 1.86% for healthy and unhealthy people, respectively.

The impact on the labor supply of raising the DRC from 4.5% to 8% is negligible. It has almost no effect on labor force participation and only causes workers to work slightly more hours after 65 (see Figure 10 (panel b)), which increases the hours worked at 65-69 by 3.14%.

Eliminating the RET beyond the NRA is responsible for the shifts in participation and hours worked sharply upward at older ages, both at the average level (see Figure 10 (panel c)) and by health status (see Figure 11 and Figure 12 (panel c)). It increases the participation and hours worked at 60-69 by 16.08% and 9.98%, respectively. In this case, individuals can work for payment and collect retirement benefits simultaneously without facing penalties, after they reach the NRA. Thus, it incentivizes the elderly to supply labor after NRA. According to the reports in Table 5, the changed earnings test rule explains the 71.1% and 86.6% observed increases in participation and hours worked by workers, respectively, from the data. Thus, eliminating the RET beyond the NRA is the main contributor to the rise in the labor supply of older workers across cohorts.

Lastly, the fifth column of Table 5 reports the effects of combining all the three documented changed Social Security rules faced by the 1950s cohort on the participation and hours worked

---

<sup>46</sup>In addition to Social Security rules, health dynamics and income tax rates change across cohorts, but their effects on the labor supply are negligible. See Appendix E for more information on the changes in health across cohorts and their impact on individual labor market behaviors.

decisions. Taking the estimated preference parameters from the 1930s, three changes in Social Security rules can explain 73.4% of the observed rise in labor force participation and 88.7% of the observed increase in hours worked at ages 60-69 across cohorts. Refer to Figure D.3 in Appendix D for the displays of the effects of combining three changed rules on the labor supply behaviors over the life cycle.

Table 5: Effects of Changing Social Security Rules on Labor Supply

## 8. Policy Experiments

Given the success of my estimated model in fitting the observed life-cycle profiles of key behaviors and explaining labor market behaviors across cohorts, I use my model to evaluate the effects of three sets of counterfactual experiments.

The first set of experiments increases the ERA by two years, from age 62 to 64, and increases the NRA by two years, from age 66 to 68, separately. The second set of experiments is to eliminate the RET for all beneficiaries under NRA. In the third set of experiments, I increase the payroll tax rate by 1.57 percentage points and reduce retirement benefits by 23%, separately, as proposed by the 2020 Trustees Report.<sup>47</sup> I measure the resulting changes in simulated labor market behaviors, consumption, savings, and Social Security claiming. The effects of these experiments are summarized in columns (2)-(6) of Table 6. I compare the effects of these reforms relative to the economy under the current social Security rules with the three changes described in the previous section (the first column). To isolate the reforms' effects, I keep other Social Security rules and model parameters unchanged when I conduct each policy experiment.

### 8.1. Shifting Retirement Age

As shown in the second column of Table 6, shifting the ERA from 62 to 64 has negligible effects on individuals' labor supply, consumption, and savings behaviors. On average, the labor force participation at 60-69 will increase but only by 0.33% (i.e., by 0.18 percentage points). In addition, there will be fewer early benefits applicants since people have to wait until age 64 to become eligible for retirement benefits (see Figure 13 (panel a)). Still, the changes are very small, only about 2.31 percentage points. These predictions are consistent with French (2005) and Imrohoroglu and Kitao (2012), which also show raising the ERA leaves individuals' key behaviors unchanged.

The third column shows the results of increasing the NRA from age 66 to 68. The reduction factor in the early 60s will get larger as the NRA is postponed.<sup>48</sup> Individuals would delay retirement to avoid receiving largely reduced benefits for the rest of their lives. As Figure 13 (panel a) displays, there will be only 0.5% of individuals applying for the benefits at the ERA of 62. In addition, individuals would save more to finance their delayed retirement. The assets when individuals reach

---

<sup>47</sup>To address the solvency problem faced by the OASI Trust Funds, the 2020 Trustee Report proposes a payroll tax rate increase of 3.14 percentage points (i.e., an increase of 1.57 percentage points for each employee and employer), from 12.4% to 15.54%; or a reduction in scheduled benefits by 23% to people who become initially eligible for benefits in 2020 or later; or some combination of these approaches.

<sup>48</sup>From the SSA, the reduction factor at age 62 is 30%, given the NRA of 67. Since there is no available information on the reduction factor at 62 if the NRA is delayed to 68, I assume that it will be further decreased by five percentage points, to 65% at age 62.

the ERA increase by 2.2%. Meanwhile, the average consumption decreases by 0.2%. Moreover, compared to the benchmark economy, postponing the NRA increases the annual hours worked at older ages by 0.72%, but its impact on the participation is small, which increases by 1.68% (i.e., by 0.91 percentage points) at 60-69. The predicted small increase in the older age participation is consistent with that of French and Jones (2011). Furthermore, Compared to the predictions in Imrohoroglu and Kitao (2012), in which raising the NRA by two years leads the participation rate at ages 60–69 to rise by 6.1 percentage points and average hours worked to increase by 0.6 percent, my model predictions have a much lower increase in the older age participation and a slightly higher increase in the average hours worked.

## 8.2. Removing Earnings Test

The fourth column displays the results of eliminating the Social Security earnings test for retired workers at the ERA of 62 or older, which means there is no earnings test for people who work for payments after collecting the benefits. This reform will induce a notable increase in the fraction of early benefits application. As displayed in Figure 13 (panel b), there will be 28 percentage points more people starting to collect the benefits at 62. In addition, individuals will work and consume more at older ages. The participation at ages 60-69 will increase by 3.37% (i.e., by 1.83 percentage points) on average, and more for unhealthy people, who will have an increase of 8.19% (i.e., 3.34 percentage points). The average consumption will be increased by 0.36%. Figure 14 (panel b) shows that eliminating the earnings test mainly affects people's consumption behaviors between the ERA and NRA, and the same for both healthy and unhealthy people.

## 8.3. Increasing Payroll Tax v.s. Reducing Retirement Benefits

Finally, the fifth and sixth columns show my model-predicted results of raising payroll tax rates by 1.57 percentage points for workers and cutting Social Security retirement benefits by 23%, respectively. Both reforms lead workers to work more hours at younger ages, 30-59, and delay retirement.

The impact of raising the payroll tax on labor supply is small. There will be a 0.22% increase in hours worked at younger ages, on average, but mainly for workers in good health (0.22% and 0.05% for healthy and unhealthy workers, respectively). It will discourage individuals' labor force participation, both at younger and older ages, decreasing by 0.07% and 1.38%, respectively. The decline in the labor supply induces less asset accumulation at the ERA and lifetime consumption, reducing by 1.46% and 0.88%, respectively. Moreover, 2.5 percentage points more workers will

<sup>2</sup> Monetary values are expressed in 2016 dollars.

wait until the NRA to collect the full retirement benefits instead of applying earlier.

Cutting benefits will increase the labor supply in both extensive and intensive margins over the life time, especially the participation at older ages, which increased by 5.10% (i.e., by 2.77 percentage points). When they reach the ERA, their average assets increase by 3.17% to finance their retirement due to fewer Social Security benefits. In addition, there will be a more significant impact on the fractions of early benefits applicants, which declined by 15.5 percentage points, and the impact is larger for unhealthy individuals. Only 1.3% of unhealthy workers will claim benefits at the ERA (see Figure D.4 in Appendix D). Those workers will wait to apply for the benefits until the NRA to avoid further reduction due to early application.

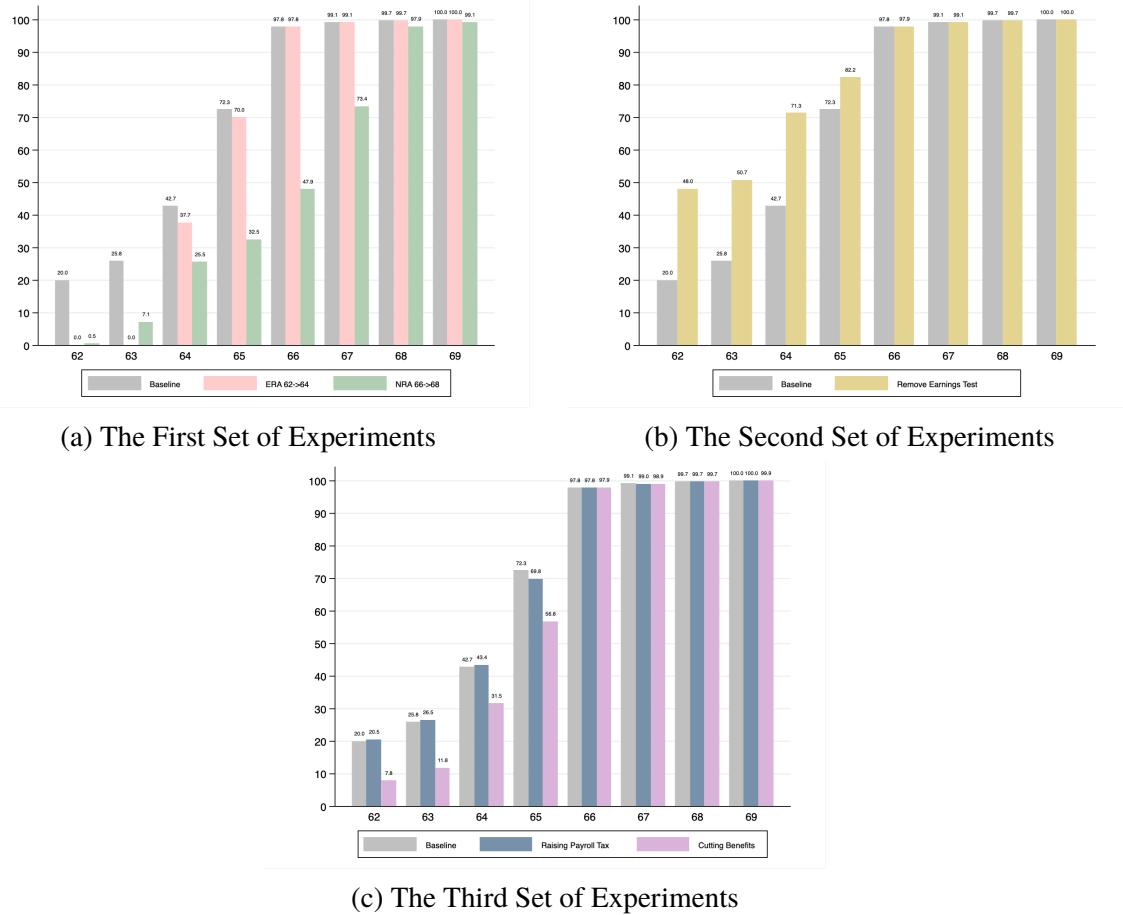

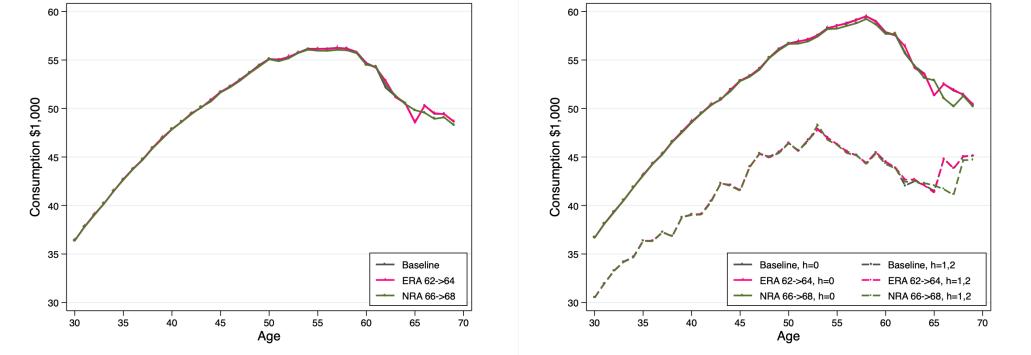

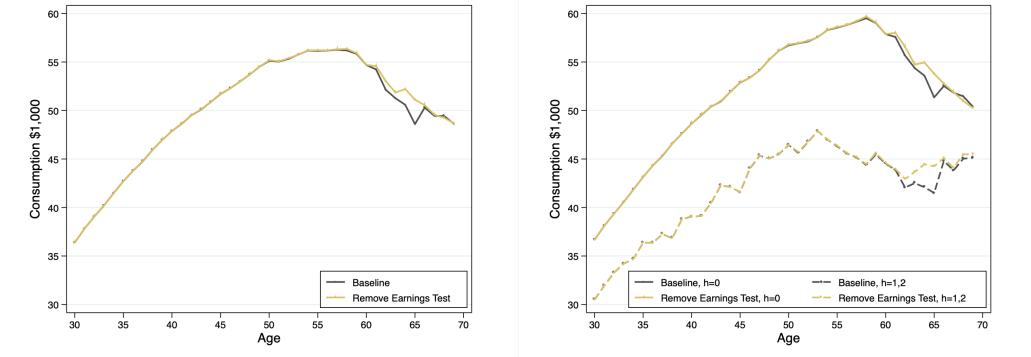

Fig. 13. Policy Experiments on Social Security Application

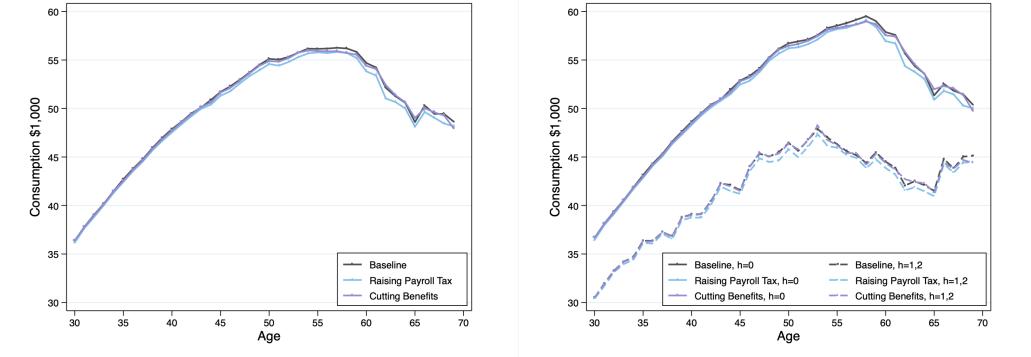

Notes: This figure illustrates model-predicted fraction of individuals who had applied for Social Security retirement benefits at ages 62-69. The gray “Baseline” bars refer to the percentage under the economy with the Social Security rules faced by the 1950s cohort. Panel a shows the effects of the first set of experiments (increasing the ERA and NRA). Panel b shows the effects of the second set of experiments (removing the earnings test). Panel c shows the effects of the third set of experiments (increasing the payroll tax and cutting the retirement benefits).

Fig. 14. Policy Experiments on Consumption

Notes: This figure illustrates model-predicted consumption over the life cycle on average (left panels) and by health status (right panels). The gray “Baseline” lines refer to consumption under the economy with the Social Security rules faced by the 1950s cohort. Panel a shows the effects of the first set of experiments (increasing the ERA and NRA). Panel b shows the effects of the second set of experiments (removing the earnings test). Panel c shows the effects of the third set of experiments (increasing the payroll tax and cutting the retirement benefits).

## 9. Conclusion

This paper documents trends in the labor supply of older men in the United States. The 1950s cohort, relative to the 1930s, supplies more labor in their 60s, in terms of both labor force participation and hours worked by workers. Further, Social Security rules faced by these two cohorts changed as well. For a more recent cohort, the NRA was postponed to age 66; the RET was eliminated beyond the NRA; and the DRC was raised from 4.5% to 8% on average.

This paper develops a structural model that captures numerous details about Social Security programs to examine the role of these documented changes in Social Security policies on the increase in the labor supply of older men across two cohorts. Compared with previous studies, my model fits the profiles of labor supply and savings by health status very well by adding heterogeneity in health, medical expenditures, and incorporating Social Security disability benefits and time-varying marginal income taxes. My model shows that the three changed Social Security rules explain most observed rises in the labor supply at older ages across cohorts. Of the three changed rules, eliminating the RET beyond the NRA provided the greatest contribution to these increases.

Further, policy experiments suggest that postponing retirement ages has small effects on individual behaviors, and raising the payroll tax will discourage labor force participation. Eliminating the RET and reducing retirement benefits would further increase the older age labor supply. However, the former will induce a notable increase in the fraction of early benefits application. In contrast, the latter will cause workers to wait to apply for the benefits until the NRA.

This paper investigates individual behaviors in response to changes in social insurance programs under limited conditions. Applying this analysis to other demographic populations, including all working men and women, would broaden the meaning of this research. Additional variables for laborers could be taken into accounts, such as marital status and education levels. Finally, applying the government retirement rules of other countries to the U.S. labor market would provide useful points of comparison.

## **Appendix A. DATA Appendix**

The bulk of my model estimation is based on the 1968 to 2015 waves of the Panel Study of Income Dynamics (PSID). I also use data from the Medical Expenditure Panel Survey (MEPS) for medical spending analysis. This section provides information for these data sets.

### **A.1. Panel Study of Income Dynamics (PSID)**

The PSID is a longitudinal study of a representative sample of the U.S. population. It provides high-quality information on, among other things, labor market behaviors, income, health status, and wealth. In 1968, about 4,800 families were first interviewed, with information gathered on these families and their descendants from that time onwards. Individuals are followed and interviewed annually (biennially since 1997) to maintain a representative sample of families. The PSID sample includes all persons living in the PSID families in 1968 plus anyone subsequently born to or adopted by a sample person.

The original 1968 PSID sample consists of 1,872 low-income families from the Survey of Economic Opportunity (SEO) and a nationally representative sample of 2,930 families designed by the Survey Research Center (SRC) at the University of Michigan. I select all individuals in the SRC sample who are interviewed in the waves 1968-2015. Since the PSID has stopped following most families from the SEO sample after 1997 and to make data more representative to the U.S. population, I drop the SEO sample. Further, I keep male household heads and their spouses, if present, and individuals age between 20 and 90. I pick male household heads born in 1920-1935 as the 1930s cohort and male heads born in 1945-1960 as the 1950s cohort. Table A.1 reports the sample selection and sample size. The resulting sample includes 984 individuals and 20,091 observations for the 1930s cohort.

I use data from the PSID to estimate the health status transition, wage process, survival probabilities, wife's earnings, initial distribution over state variables, and the moment conditions that my model is estimated to match.

Table A.1: PSID Sample Selection

Selection	Individuals	Observations
Initial sample	76,880	3,075,200
Non-SEO sample	36,430	1,457,200
Household heads and spouse if present	21,225	265,743
Male household heads	10,472	123,650
Age 20 to 90	10,407	122,730
The 1930s cohort	984	20,091
The 1950s cohort	2,844	45,945

Table A.2: MEPS Sample Selection

Selection	Individuals	Observations
Initial sample	259,263	491,795
Household heads	130,978	231,866
Age above 20	125,587	222,495
With insurance information at 25-65	121,385	213,005
Non-missing health status	120,731	211,709

## A.2. Medical Expenditure Panel Survey (MEPS)

The MEPS is a nationally representative survey of families, individuals, their medical providers and employers across the United States. It contains individuals of all ages but age is top coded at age 85. The medical spending reported in the MEPS is at the individual level and cross-checked with medical providers and insurance companies, which improves the accuracy of the data. I use data from the 1999-2012 waves of MEPS, drop observations with missing values of age, medical spending, health insurance information during the working periods, or health status, and keep household head above age 20 only. The resulting sample comprises 120,731 persons and 211,709 person-year observations.

I use data from the MEPS to estimate the life-cycle profiles of out-of-pocket medical expenses by health status for a representative population.

## Appendix B. Numerical Methods

The decision rules are solved numerically using value function iteration, starting at the period  $T$  and working backward to the first period. Recall that decision rules solve the following problem :

$$\begin{aligned} V_t(X_t) &= \max_{c_t, n_t, b_t} \{ u(c_t, l_t) + \beta s_{t+1} E_t[V_{t+1}(X_{t+1})] + \beta(1 - s_{t+1}) b(a_t) \} \\ &= \max_{c_t, n_t, b_t} \left\{ \frac{1}{1-\nu} \left( c_t^\gamma [L_t - n_t - \theta_p^{h_t} p_t - \phi \mathbb{1}_{\{h_t \neq 0\}}]_t^{1-\gamma} \right)^{1-\nu} \right. \\ &\quad \left. + \beta s_{t+1} \int V_{t+1}(X_{t+1}) dF(X_{t+1}|X_t, t, c_t, n_t, b_t) \right. \\ &\quad \left. + \beta(1 - s_{t+1}) b(a_{t+1}) \right\} \end{aligned}$$

At time  $T$ , consumption decision  $c_T$  is made by solving the above problem  $V_T(X_T)$  with the terminal value  $V_{T+1} = B(a_{T+1})$ . Given the decision rules and value function at time  $T$ , I then solve decision rules at time  $T - 1, T - 2, \dots, 0$ , using backward induction.

I discretize the state variables  $\chi$  into a finite number of points within a grid. I directly compute the value function at these points and integrate the value function with respect to the innovation of wages using five-node Gauss-Hermite quadrature (see Judd (1998)). Also, I use linear interpolation within the grid and linear extrapolation outside of the grid to evaluate value function at points that can not be directly computed.

The grid consists of 30 asset states,  $a_j \in [\$0, \$660000]$ ; 10 wage states,  $w_j \in [\$3, \$60]$ ; 10 AIME states,  $AIME_j \in [\$2000, \$43800]$ ; 2 Social Security application states; and 3 health states (good health, bad health, disabled state).<sup>49</sup> In particular, I solve the value function at 9,000 different points at the first stage; 18,000 points at the second stage; and 900 points at the third stage. Following French (2005), since changes in assets, wages, and AIME are intended to cause larger behavioral responses at low levels of these state variables, the grid is more finely discretized at these levels. In addition, I discretize the the consumption and hours worked decision space and find the optimal decisions by searching over the grid. There are 180 points for consumption, and the hours worked grid is broken into 300-hour intervals.

I then use the decision rules to generate simulated life-cycle histories of individuals using forward induction. For instance, given the realized state variables  $X_0$ , I can find an individual's decision at time 0 using the decision rules at  $t = 0$ . Then given time-0 decisions, the state variables  $X_1$  can be obtained using  $\chi_0$  and shocks at time 1, the same for  $t = 2, \dots, T$ .

---

## Appendix D. Supplemental Figures

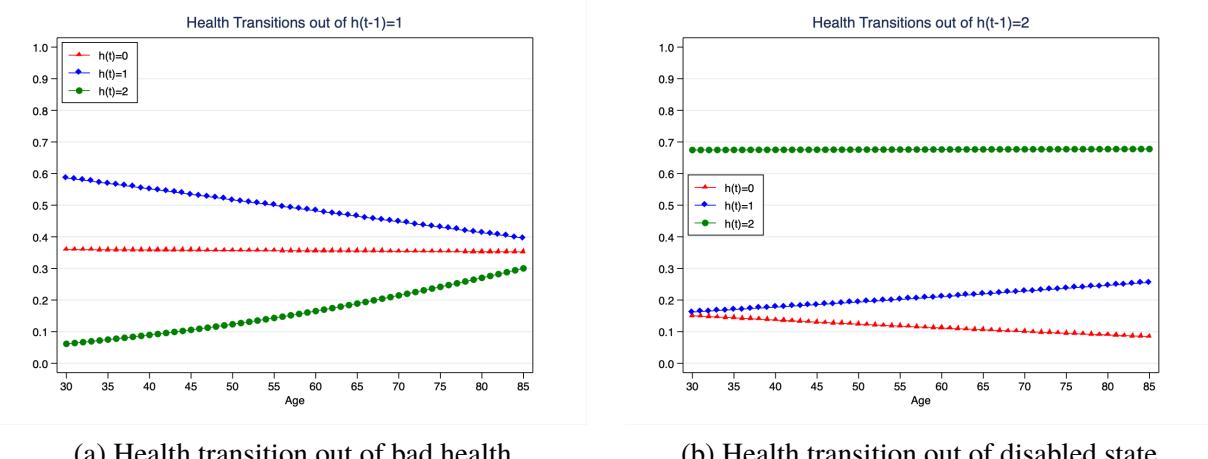

(a) Labor force participation trends

(b) Hours worked trends

Fig. D.1. Labor Supply Trends of Men by Age Groups

Notes: Panel a shows the trends in labor force participation by age groups. Panel b shows the trends in hours worked conditional on participation by age groups.

Source: March Current Population Survey (through IPUMS, see Flood et al. (2020)), author's calculations.

(a) Health transition out of bad health

(b) Health transition out of disabled state

Fig. D.2. Remaining Health Transitions

Notes: Panel a shows the probabilities of transitioning out of bad health. Panel b shows the probabilities of transitioning out of disability status. The red line shows the transition probabilities to good health. The blue line shows the transition probabilities to bad health. The green line shows the transition probabilities to disability status.

Source: Panel Study of Income Dynamics, author's calculations.

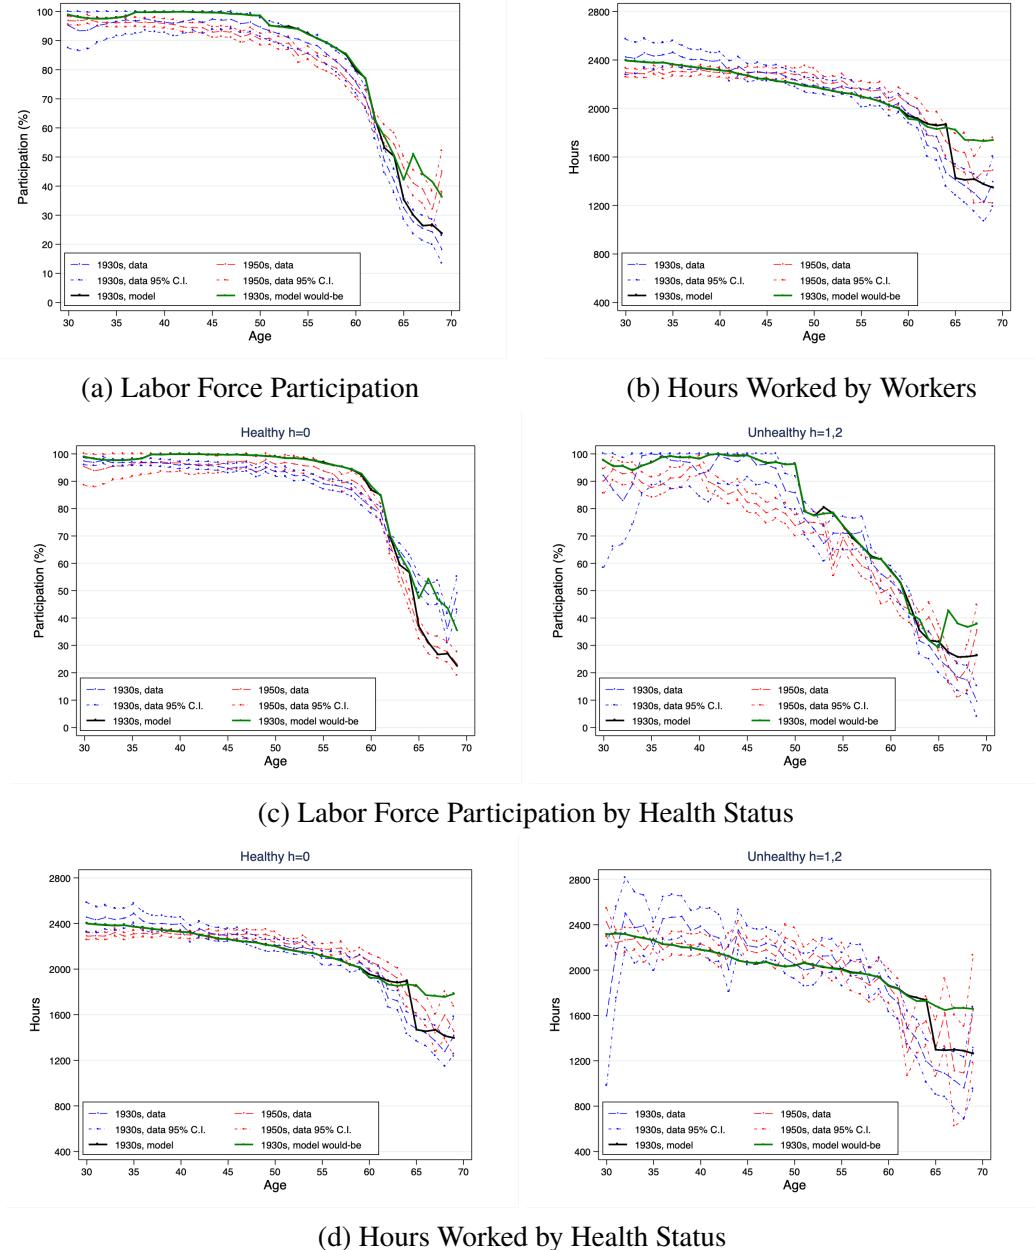

Fig. D.3. Model v.s. Data Profiles: Effects of Changing Three Social Security Rules

Notes: Panel a and panel b show the effects on the labor behaviors at the average level. Panel c and panel d show the effects by health status. The black (green) lines represent the model-simulated profiles for the 1930s cohort before (after) implementing policy changes. The blue (red) dashed lines represent the data profiles with 95% confidence intervals for the 1930s (1950s) cohort.

Data Source: Panel Study of Income Dynamics, author's calculations.

Fig. D.4. Policy Experiments on Social Security Application by Health Status

Notes: This figure illustrates model-predicted fraction of healthy individuals (left panels) and unhealthy individuals (right panels) who had applied for Social Security retirement benefits at ages 62-69. The gray “Baseline” bars refer to the percentage under the economy with the Social Security rules faced by the 1950s cohort. Panel a shows the effects of the first set of experiments (increasing the ERA and NRA). Panel b shows the effects of the second set of experiments (removing the RET). Panel c shows the effects of the third set of experiments (increasing the payroll tax and cutting the retirement benefits).

## Appendix E. Effects of Non-Social-Security Changes

In addition to Social Security rules, health dynamics and income tax rates also vary across cohorts. In this section, I explore the effects of these changes on labor market behaviors.

### E.1. Effects of Changing Health Dynamics

Health dynamics change across cohorts. For instance, Figure E.1 (panel a) displays the age-specific health transition out of good health status  $Pr(h_t|h_{t-1} = 0)$  for the 1930s cohort (solid lines) and the 1950s cohort (dashed lines). Compared to the older cohort, individuals born in the younger cohort face higher probabilities of staying in good health and lower probabilities of transitioning from good health into bad health or disability status over the life cycle. As a result, relative to the 1930s cohort, the fraction of individuals in good health is higher, whereas that of people with disability is lower in the 1950s cohort (see Figure E.1 (panel b)).

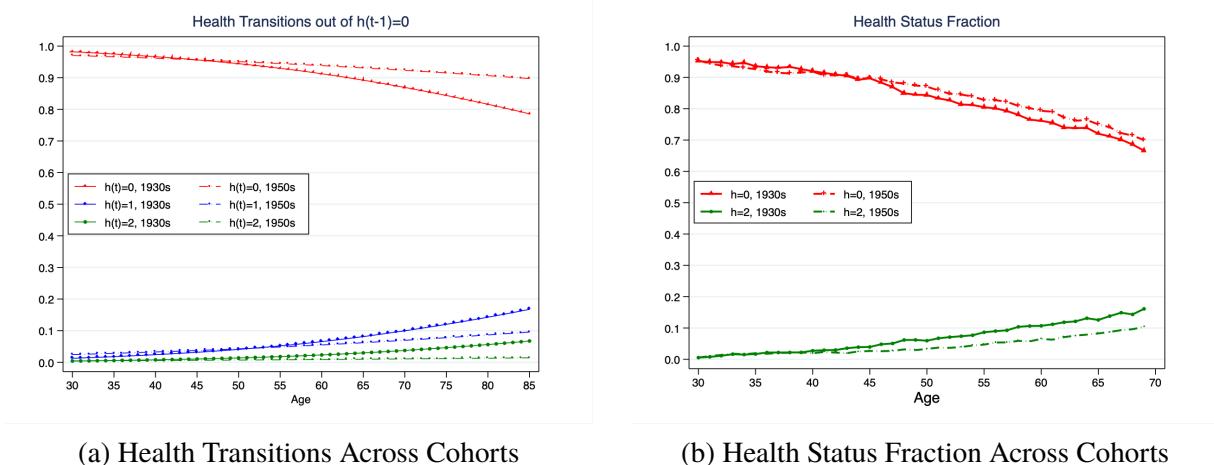

Fig. E.1. Health Dynamics Across Cohorts

Notes: The solid lines (dashed lines) indicate probabilities/fraction for the 1930s (1950s) cohort. Panel a: The red line shows the transition probabilities from good health to good health. The blue line shows the transition probabilities from good health to bad health. The green lines show the transition probabilities from good health to disabled state. Panel b: The red (green) lines show the fraction of individuals in good health (disabled state).

Source: Panel Study of Income Dynamics, author's calculations.

Then I use my estimated model to evaluate the impact of changing health dynamics on the rise of older workers' labor supply across cohorts. Taking the estimated preference parameters from the 1930s model as given, I replace the healthy transition matrix of the 1950s cohort and simulate

how the 1930s cohort would behave if they had the same values for those factors as the 1950s cohort. Figure E.2 displays the effects of changing health dynamics on the labor market behaviors over the life cycle and compares the model-simulated changes with the data profiles across cohorts.

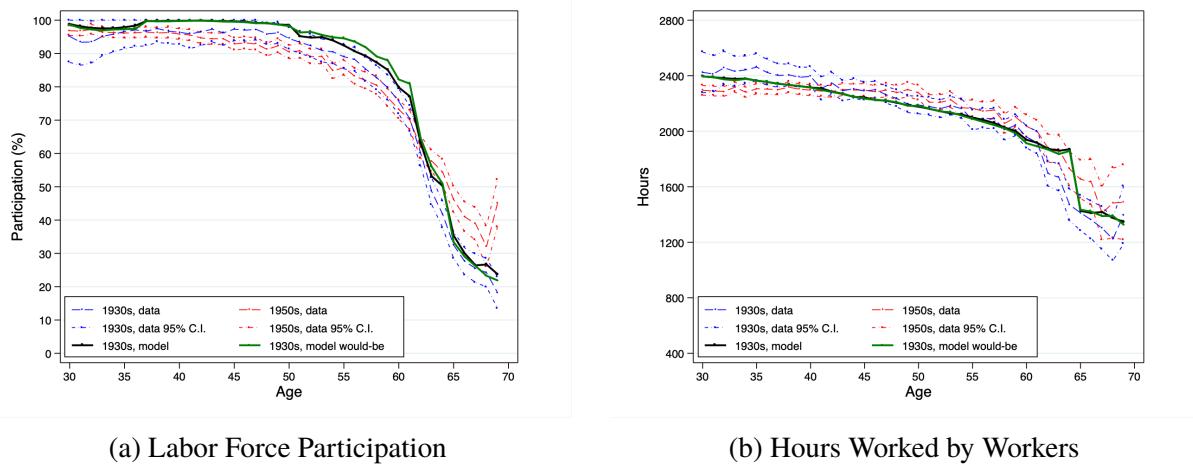

Fig. E.2. Model v.s. Data Profiles: Effects of Changing Health Dynamics

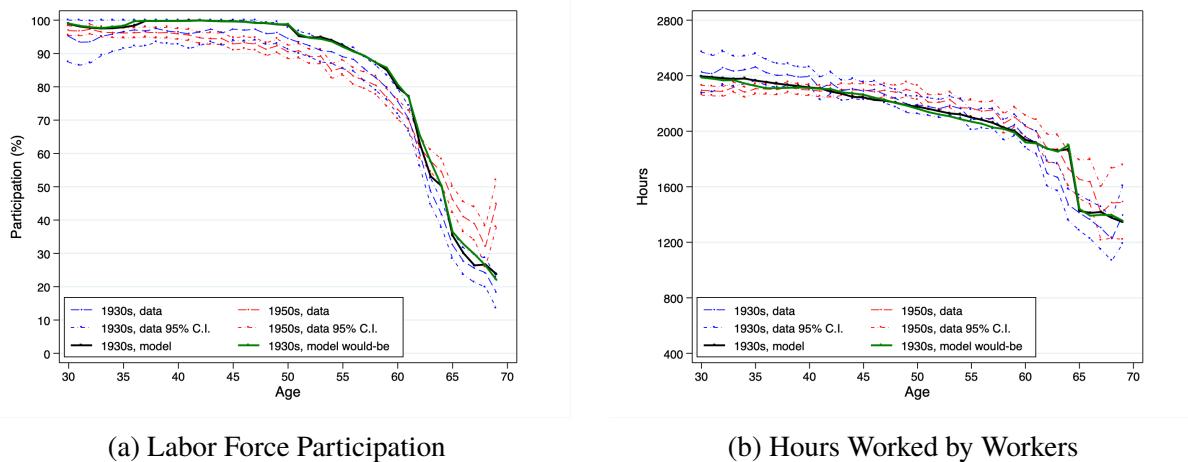

Notes: The effects on the labor behaviors at the average level. The black (green) lines represent the model-simulated profiles for the 1930s cohort before (after) implementing new health dynamics. The blue (red) dashed lines represent the data profiles with 95% confidence intervals for the 1930s (1950s) cohort.

Data Source: Panel Study of Income Dynamics, author's calculations.

The impact on the labor force participation is small. On average, it only increases the participation rates at ages 60-69 by 0.56% (i.e., by 0.003 percentage points). In addition, changed healthy dynamics have negligible effects on hours worked by workers. It reduces the annual hours worked by 0.67% (i.e., by 11 hours) at ages 60-69.

## E.2. Effects of Changing Marginal Taxes

As documented in, e.g., Borella et al. (2019a), the progressive income taxes change every year for a specific cohort. Hence, marginal tax rates on income faced by two cohorts at each age change as well. Then taking the estimated preference parameters from the 1930s model as given, I replace the income tax rates of the 1950s cohort, that is estimated following Borella et al. (2019a) and using the data from the PSID, and simulate how the 1930s cohort would behave if they had the same values for those factors as the 1950s cohort. Figure E.3 displays the effects of changing income tax rates on the labor market behaviors over the life cycle.

(a) Labor Force Participation

(b) Hours Worked by Workers

Fig. E.3. Model v.s. Data Profiles: Effects of Changing Marginal Tax Rates

Notes: The effects on the labor behaviors at the average level. The black (green) lines represent the model-simulated profiles for the 1930s cohort before (after) implementing new marginal tax rates on income. The blue (red) dashed lines represent the data profiles with 95% confidence intervals for the 1930s (1950s) cohort.

Data Source: Panel Study of Income Dynamics, author's calculations.

Similar to the effects of changing health dynamics across cohorts, the impact of changing marginal income tax rates on the labor force participation and hours worked is negligible. More specifically, it only increases the participation rates and annual hours worked at ages 60-69 by 0.01 percentage points and by 0.3 hours, respectively.
